Dr. G. Melville Black of Denver, in a paper on "Ocular Prothesis," called attention to the recent suggestion of Snellen regarding different forms of artificial eyes. The shell heretofore generally used is designed to be worn over a shrunken eyeball, and not to fill up the orbit after an enucleation. There are also needed a concavoconvex form of artificial eye to be worn over a small stump and a double convex form to properly occupy the orbit after enucleation, Artificial eyes of the latter forms not being obtainable yet in this country the speaker had resorted to the expedient of filling in the cavity of the ordinary shell with a preparation of wax (Gilbert's temporary stopping) used by dentists. This had proven quite satisfactory in preventing the unsightly sinking of the artificial eye, the accumulation of discharges behind it, and irritation of the conjunctiva by the formation of a vacuum beneath the shell.

OPERATION FOR GALL-STONES.

Dr. I. B. Perkins of Denver reported three cases of distention, inflammation, and sepsis arising from obstruction of the ducts by gall-stones. The patients were cured by operation. The greater frequency of gall-stones among women (more than two to one) is probably due to constriction of the abdomen by customary styles of dress, as well as to a more sedentary life. The speaker had performed the operation of incision, removal of the contents of the gall-bladder, and drainage, with closure of the opening subsequently. He believed the operation of immediate closure of the gall-bladder and dropping it back into the abdomen is rarely applicable and that it ought not to be called the "Ideal" operation. Of the stitches passing through the abdominal wall to close the incision, those opposite the opening into the gall-bladder are made to enter its wall and then emerge from it again like a Lembert suture before crossing the incision. Two or three of these stitches at the center of the incision are left untied, and the gaping wound packed with gauze to ensure free drainage. When drainage is no longer needed the edges of the abdominal wound are slightly freshened and the stitches tied without the need of anesthesia. The inversion of the edges of the incision in the gall-bladder secures prompt union.

DR. JOHN B. ROBERTS of Philadelphia was favorably impressed with Dr. Perkins' plan of closing the wound. When a gall-stone is impacted in the common duct, however, it would be extremely difficult to dislodge it by any such operation. He suggested that the duct might be followed down to its entrance into the duodenum and an opening made in the duodenum opposite this point. A probe could then be introduced through the mouth of the duct and the obstructing stone pushed back into the gall-bladder and removed. The dilatation of the duct above the point of obstruction would commonly render the dislodgment of the obstruction not difficult.

APPENDICITIS WITH ANOMALOUS POSITION OF THE APPENDIX.

DR. A. J. HOSMER of Salt Lake City exhibited a boy operated on for appendicitis in whom through the usual incision in the right iliac region, no trace of the appendix or head of the colon could be found. A mass of exudate, however, could be felt far up and to the right. A median incision was made and the gangrenous appendix removed from the midst of this mass. In this case the pain was referred to the left side.

SUPRARENAL EXTRACT IN SURGERY OF THE EAR, NOSE, AND THROAT.

DR. W. W. BULETTE of Pueblo reported an experience with this agent in 201 cases, 137 of nasal, 46 of throat, and 18 of ear disease. It produces anemia of the tissues, reduces swelling and prevents hemorrhage that would otherwise be very troublesome by obscuring the field of operation. It also aids in prolonging local anesthesia, which is cut short by the hemorrhage washing away the cocain. With its help operations can be performed without pain and loss of blood. There are no unpleasant effects and there is little secondary hemorrhage. Since employing it, cases presenting symptoms of cocain poisoning have been fewer. It reduces to a minimum the patient's dread of operation.

THE BOTTINI OPERATION FOR HYPERTROPHY OF THE PROSTATE.

DR. LEONARD FREEMAN of Denver reported eight cases of enlarged prostate in which Bottini's operation was performed. The instrument consists of a platinum galvanocautery knife arranged like the male blade of a lithotrite. Any general burning of tissue in contact with the instrument is prevented by a stream of ice-water circulating through it. The operation causes little after-pain or bleeding. Five of the eight patients were practically cured. One patient improved at first and still has no residual urine, but again suffers from pain and frequent urination as badly as ever, and cancer is now suspected. The speaker believes this the best operation yet proposed for enlarged prostate. Few men submit cheerfully to castration or vasectomy. Bottini's operation causes no external wound. It can usually be performed under local anesthesia. In his cases general anesthesia was used but once. The burned surfaces are practically sealed against absorption. The benefit is immediate. There are few relapses. The patient can move about within a day or two. The mortality of the operation (generally 5 per cent.) is less than by other methods of operation.

DISEASES OF THE MASTOID.

DR. C. K. COLE of Helena, reported four cases of mastoid disease illustrative of sixteen that he had seen during the last twenty months. Such cases are essentially surgical. He advocated thorough opening of the mastoid and irrigation with not less than 2 to 4 quarts of hot sterilized water or antiseptic solution. The periosteal incision may sometimes be useful in young patients. In extreme cases multiple openings are to be advised.

TOXIC CAUSES OF INSANITY.

DR. HUBERT WORK of Pueblo called attention to the generation within the body of poisons capable of causing mental alienation. Loss of weight and anorexia occur so constantly in connection with certain psychoses as to suggest at least a common cause. Some of the most distressing symptoms of dyspepsia are mental. It is certain that insanities do result from prolonged digestive disturbances. Auto-infection from the alimentary canal may alone be the cause in many cases. He reported four illustrative cases in which treatment directed to the source of the toxic influence brought about a cure of the mental symptoms. In the first, a case of digestive disturbances, a cure was accomplished in three months. The second patient, ill with rheumatism was cured in eighteen months. The third was a case of chronic cystitis and the patient was cured in four months. The fourth patient, whose illness was due to hepatic derangement, was cured in two months. In no disease is proper medical treatment more needed at the beginning than in insanity.

AUTO-INTOXICATION AND BLOOD MORPHOLOGY IN RELATION TO OPERATIONS.

DR. P. S. KEOGH of Salt Lake City discussed the bearing of these conditions on the preparation of a patient for a surgical operation. The older surgeons well knew that complications followed less frequently when the patient had been prepared for operation by catharsis. Symptoms of indigestion and gastro-intestinal disease should always be carefully looked for. Examination of the urine might reveal a deficient elimination of solids. General anesthetics increase the danger from auto-intoxication. The examination of the blood, particularly with reference to the percentage of oxyhemoglobin and the condition of leucocytosis, gives very important evidence regarding the patient's power of resistance.

CASES OF INFECTION BY THE BACTERIUM COLI.

DR. J. N. HALL of Denver stated that this organism, at first regarded as only a harmless inhabitant of the alimentary canal, is now known to be one of the most important pathogenic bacteria. Probably the name is now applied to a whole group of bacteria representing varying degrees of virulence and not to a single species. He reported two fatal cases of infection, both patients being males. The first patient, after twenty-four-hours' retention of urine, presented great numbers of colon bacilli.

Pleuritis, bronchopneumonia, pericarditis, a purpuric eruption, pyelitis, and perinephritic inflammation ensued. In the case of the second patient there was a purpuric eruption and abscesses were scattered over the body. The bladder was distended with acid, foul-smelling urine, containing sugar and loaded with bacilli. Gas was generated within the bladder. The spleen and liver were found to be septic. The kidneys were also involved and a large abscess was found behind the sternum.

THE EARLY DIAGNOSIS OF TUBERCULOSIS.

DR. A. M. HOLMES of Denver said that there are early evidences of this disease, and if these are heeded recovery may be brought about. Loss of appetite and weight, gastric disturbances, dyspnea, and persistent cough should lead to careful and repeated examinations. The importance of the early examination of the sputum he thought has been over-rated. If the bacilli are found, the evidence would be conclusive, but they may exist in concealed foci of infection a long time before making their way into the sputum. He regarded subnormal morning temperature and "cog-wheel" respiration as important symptoms; but not hemorrhage. Early in the disease the study of the blood is more important than the study of the sputum, especially the examination of stained blood-films with a differential count. There is no excuse for delay in the diagnosis of tuberculosis. A certain test exists in the reaction produced by tuberculin. The speaker employs at first an injection of 1 milligram, and if no reaction follows this three days later 3 milligrams are injected, and if this produces no effect, 5 milligrams. The injection should be made in the evening and the reaction commonly occurs six to twelve hours later.

The following officers were elected for the ensuing year: President, Charles K. Cole of Helena, Montana; vice-presidents, Leonard Freeman of Denver and R. H. Reed of Wyoming; treasurer, Charles G. Plummer of Salt Lake City; recording secretary, Donald Campbell of Butte, Montana; corresponding secretary, S. D. Hopkins of Denver. Drs. Judson Daland and John P. Roberts of Philadelphia were elected Honorary Members. The place selected for the next meeting was Butte, Montana, and the time the last week of August, 1900.

REVIEWS.

A TREATISE ON HUMAN PHYSIOLOGY. For the Use of Students and Practitioners of Medicine. By HENRY C. CHAPMAN, M.D., Professor of the Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College of Philadelphia. New (2d) edition thoroughly revised. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

THE revision of this work as it formerly appeared has been mainly in the way of numerous additions and subtractions, rather than any comprehensive alteration in its general character. The statement in the author's preface that "there is a want felt by students and practitioners of medicine for a systematic work, based upon comparative and pathological anatomy, *clinical medicine* . . . as well as upon experimental research," might lead one to hope that the author, by introducing frequent comparisons with phenomena presenting conditions other than those strictly physiological, had created for his work an acceptability which, in this feature, such standard and thoroughly comprehensive treatises as Foster's does not possess. In this hope the purchaser of Dr. Chapman's book would be disappointed. It is a text-book of pure physiology.

While the work presents no unusual features it is a very scholarly presentation of the essential data of physiology, carefully arranged and logically set forth. The nervous system is considered at great length and in great detail. We do not condemn the author for thus occupying so large a part of his book, except in so far as it is unwarrantably disproportionate to the space devoted to other equally important subjects. The urine, and especially its chemistry, is in particular too briefly disposed of.

The appearance of the book is excellent; the illustrations are numerous and carefully executed.

A MANUAL OF SURGICAL TREATMENT. By W. WATSON CHEYNE, M.D., F.R.C.S., F.R.S., Professor of Surgery in King's College, and Surgeon to King's College Hospital, London; and F. F. BURGHARD, M.D., M.S. (London), F.R.C.S., Teacher of Practical Surgery and Surgeon to King's College Hospital, London. Vol. I. Philadelphia and New York: Lea Brothers & Co., 1899.

THERE is no question that the authors have given a work to the profession which was needed. The preliminary and after-treatment of surgical patients has assumed an importance which no operator can afford to neglect. These are as essential to the recovery of a patient from a surgical operation as the operative measures themselves. Hospital internes and operating surgeons are the only ones who fully realize this important factor in the treatment of surgical diseases. For such physicians as operate in centers removed from hospital facilities or who operate only occasionally, for the general practitioner who is called upon to do surgical work, and above all, for the medical student, a work of this kind is indispensable. It can be read with profit, too, by every one who is interested in surgical procedures.

In the first volume the authors deal largely with general principles. They discuss inflammation, acute suppuration, ulceration, and gangrene, in the order named. A lucid, practical chapter on anesthesia by Dr. J. Frederick Silk follows, which is a splendid review of the subject. The general treatment of wounds of surgical and accidental etiology is next considered with very clear and practical articles on hemorrhage, shock, and syncope. The constitutional diseases are fully considered in succeeding chapters and the volume closes with a discussion of the varieties of tumors and their treatment.

The book differs from all other works on surgery in the English language by confining itself strictly to practical considerations. There is no theory of disease or its causation, nothing but the treatment of patients suffering from surgical disease once the diagnosis is made. The treatment of patients before and after operation, includ-

ing anesthesia and the conduct of the treatment in the face of any of the emergencies of surgical practice, are fully set forth. The vast material on which the authors have drawn for their deductions gives the book an unusual value. It is a work of the highest worth from literary and scientific standpoints and is of corresponding value to every member of the profession. It is one of the few books of which one can truthfully say that "it should be found on the desk of every physician."

The book-making is above the average, but some of the illustrations lack in clearness. The succeeding volumes will be awaited with interest.

STEREOSKOPISCH-PHOTOGRAPHISCHER ATLAS DER PATHOLOGISCHEN ANATOMIE DES HERZENS UND DER GRÖSSEREN BLUTGEFASSEN, with fifty photographic reproductions of original impressions. By DR. G. SCHMORL. Munich: J. F. Lehman, 1899.

AS its name indicates, this is a series of double photographs mounted two by two on cards and meant to be viewed with the stereoscope, which does actually in this case produce a very illusive sense of solidity in the pictures. The cards are done up neatly in a cloth-bound box and would be an excellent means of demonstrating the pathology of the heart where actual specimens could not easily be obtained. The idea of stereoscopic views in pathology is new and is well put into effect in this case.

INTERNATIONAL CLINICS. A Quarterly of Clinical Lectures on Medicine, Surgery, Neurology, Gynecology, Obstetrics, etc., with specially prepared articles on Treatment and Drugs, by Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain and Canada. Edited by JUDSON DALAND. Vol. II. Ninth series. Philadelphia: J. B. Lippincott Co., 1899.

THE July number of the *International Clinics* thoroughly maintains the reputation of this well-known quarterly, especially as regards the contributions from foreign clinicians. We note the names of Fournier, Grauchier, Jaccond, and Brocq of Paris, those of Von Bergman, König, Frankel, Grawitz, Lassar, Gutzman and Holländer of Berlin, and Kovacs of Vienna among the contributors to this volume. The variety of matter is excellent and the clinics have been chosen with good judgment and with an eye to their practical interest for the general practitioner in the varied problems that come up for his solution from day to day.

Brocq of Paris, in his article on the treatment of carbuncles and furunculosis details his experience with brewer's yeast in aborting carbuncles and in preventing recurrent furuncles. He had occasion to try the remedy on himself for carbuncles with which he had been affected nearly every year. It proved an excellent remedy, aborting a carbuncle that had begun to develop and acting as a prophylactic against further attacks. He has had the same success with patients who have had at least one carbuncle a year for many years, in one case over thirty years. The same result has followed its use in persistent furunculosis, and Brocq considers that yeast (for he has found the ordinary cake yeast of the shops almost as effective as brewers' yeast), is as much a specific for cutaneous suppurative conditions as mercury for syphilis, or quinin for malaria.

Dr. Hollander of Berlin presents a method for using superheated air as a hemostatic and as a cauterizing agent. The method commends itself by its simplicity, a coiled metal tube and a Bunsen-burner being the only apparatus necessary. Dr. Holländer has found it useful, especially in arresting parenchymatous bleeding, as in resection of the liver for cancer. He has employed superheated air as a therapeutic agent for inveterate cases of lupus vulgaris, and judging from the photographs of patients before and after treatment, which are given, the results have been most encouraging. Professor Ernest Grawitz presents an excellent practical review of the present position of German medical thought as to pernicious anemia. Professor König of Berlin has an interesting clinical lecture on wounds in the cardiac region and strictures of the rectum. A striking position taken by König with regard to rectal strictures is that the form of stricture which in women sometimes breaks down and causes a good deal of destruction of tissue, is really gonorrheal in origin and not syphilitic as has been supposed.

Dr. Gutzmann of Berlin gives an excellent presentation of the causes, the forms, and the treatment of stuttering. We do not think that the subject has ever been put so clearly and completely in so few pages.

The present volume is not as well printed as its predecessor. The typographic standard has been very high in the past. The illustrations in the present number are quite as good as usual, but the printing leaves something to be desired.

THE MINERAL WATERS OF THE UNITED STATES AND THEIR THERAPEUTIC USES. By JAMES K. CROOK, A.M., M.D., Adjunct Professor of Clinical Medicine and Physical Diagnosis, New York Post-Graduate School. Philadelphia and New York: Lea Brothers & Co., 1899.

THERE is undoubtedly a distinct field of usefulness for a work of this character. The fact that this is the only one dealing with this subject gives it a unique place in medical literatnre. The book is divided into two parts. The first deals with the history and origin of mineral springs, the various classifications, an analysis of the components of springs in general, the therapeutic uses of mineral waters, and two very excellent chapters on baths, and douches and their employment. In the second part the author takes up in alphabetical order according to States, the mineral springs they contain. Further he gives an analysis of the waters of each spring derived from various sources, the means of access to every resort, and the special adaptability of the different waters to disease and the proper therapeutic employment of each kind of water. The various bath resorts are fully and accurately described as well.

There is a vast fund of information within the covers of the book and while the authors must have been industrious he has made an effort to be accurate also. As far as we are able to judge from numerous comparisons he

has been successful in this particular too. This is a work which is certain to be popular for the information which most physicians have on the subject is very meager and is based on hearsay. Too often, certain baths or springs are recommended to patients without the slightest knowledge on the part of the recommending physician. In this volume the author has done for America what the Weber's have done for Europe. The book-making is beyond reproach.

THE MECHANICS OF SURGERY, COMPRISING DETAILED DESCRIPTIONS, ILLUSTRATIONS AND LISTS OF INSTRUMENTS, APPLIANCES AND FURNITURE NECESSARY IN MODERN SURGICAL ART. By CHARLES TRUAX, Chicago, 1899.

THIS is a large volume containing over 1000 pages of well printed and profusely illustrated matter. The author presents reliable and detailed information on the subject of medical and surgical instruments and appliances. It is not a price-list catalogue, but illustrates and describes such mechanical appliances as research and experience have proved best adapted to the purposes for which they are designed. It is full of valuable information and suggestion, especially for those members of the profession who do not have ready access to surgical instrument shops.

THE THROAT AND NOSE AND THEIR DISEASES. By LENNOX BROWNE, F.R.C.S.E., Senior Surgeon to the Central London Throat, Nose, and Ear Hospital. Assisted in Anatomy by MAYO COLLIER, M.S., F.R.C.S.; in Nervous Diseases by JAMES CAGNEY, M.D.; in Histopathology by WYATT WINGRAVE, M.R.C.S. Fifth edition. Illustrated mostly from designs by the author. London: Bailliere, Tindall & Cox, 1899.

THE study of this volume of almost a thousand pages is most satisfactory. Although the distinguished author has allied himself with others for the elaboration of technical subjects, the work stands as a monument to his learning, his experience, and his industry. While it is a work which can with profit be read and digested by every physician who is in the habit of treating diseases of the nose and throat, it is, and we think, will remain for a long time, a standard authority on the special subject with which it deals.

The anatomy and physiology of the larynx, pharynx, and nose are first considered; then follow chapters on the examination of these organs, general symptomatology, and an exhaustive chapter on treatment. The general etiology and pathology of throat diseases are next discussed, an entire chapter being devoted to the bacteriology of the subject. The pathology of the nose is similarly treated, and then follow chapters dealing successively with the individual diseases of the nose and throat. The final chapters are given over to the diseases of the accessory cavities of the nose and aural maledies associated with nasopharyngeal disease.

It is surprising to note that in the chapter devoted to diphtheria the author, while not directly opposing the use of antitoxin, does not view its use as a specific as we in this country are accustomed to regard it. He believes that the value of the antitoxic serum depends more upon its dynamic properties as a serum that upon the antitoxin which it contains. The author has thus, at least, made a step forward during the past two years.

The whole subject of pharyngeal and nasal diseases is illumined by this work and we regret that it is impossible to give it more extended review. In closing we would note that American writers are freely cited throughout the book.

The illustrations are more than usually elaborate and aid decidedly in giving the book a distinguishing mark. As a text-book we know no equal in the English language.

THERAPEUTIC HINTS.

Painless Injections of Mercurials.—BAZIN states that if pure guaiacol be incorporated with the oil used as a medium for intramuscular injections of mercurials the process is rendered practically painless. He gives this formula, the guaiacol being employed in the proportion of three per cent.

℞	Hydrarg. iod. rubr.	gr. viii
	Guaiacol pur.	*m.* xlv
	Ol. olivæ ster.	ʒ iii.

M. Sig. For hypodermic use.

The injections are practised daily or every other day, 30 minims representing approximately gr. ⅙ of the biniodid. The needle is inserted perpendicularly to the skin, pushed in to its full length, and the liquid injected very slowly, the buttocks being chosen preferably for the operation.

For Alopecia Areata.—BALZER praises the efficacy of lactic acid in overcoming this disease. It is applied on a bit of absorbent cotton to the affected areas, with light friction until the skin appears reddened. This is repeated daily, but if the irritation produced become too intense, possibly causing the formation of crusts, the treatment should be suspended and irritation subdued by applications of boric vaselin. As soon as possible the lactic-acid treatment should be resumed. Antisepsis of the scalp is secured by bathing with Van Swieten solution. New hair should appear in two to three weeks and a complete cure be anticipated in two to three months. When the beard is affected the process of cure is more prolonged.

For the Pruritus of Senility.—

℞	Sodii bromidi } aa Sodii salicyl. }		ʒ iv
	Sodii iodi } aa Sodii acetat. }		ʒ ii
	Inf. gentianæ		℥ ii.

M. Sig. One teaspoonful in water after meals.

Locally: Bathing with a hot solution of corrosive sublimate, 1–2000; of acetic acid, 1 per cent., or of potassium permanganate, 2 per cent., or stronger. This is followed by inunction with:

℞	Menthol	gr. viii
	Guaiacol	ʒ iss
	Ac. salicyl.	ʒ ss
	Lanolini	℥ i.

M. Sig. External use.—*Lavallée.*

ORIGINAL ARTICLES.

ROENTGEN-RAY EXAMINATIONS IN INCIPIENT PULMONARY TUBERCULOSIS.[1]

BY FRANCIS H. WILLIAMS, M.D.,
OF BOSTON, MASS.

DURING the past three years I have seen about 275 cases of pulmonary tuberculosis, and I have examined about 165 of the patients by means of the X-rays.[2] In making these X-ray examinations my attention was early directed to the darkened apex and the shortened excursion of the diaphragm, which were signs common to nearly all of these cases, and it seemed to me that these appearances warranted further study with reference to their usefulness in detecting pulmonary tuberculosis in the incipient stage.[3] It is this part of my work with the X rays that I am to have the pleasure of laying before you this morning, or, rather, such portions of it as may be presented in the few minutes at my disposal. I will first ask your attention to a few incipient cases, in choosing which I have taken only those in which the diagnosis was confirmed by finding the tubercle bacilli or by reaction to the tuberculin test. I have divided these patients, for convenience, into two groups: First, those with slight physical signs, but no râles except in Case II. Second, those without physical signs—that is, whose lungs had been found normal by auscultation and percussion. In some of these an X-ray examination was made for the purpose of determining the size of the heart, and not because the lungs were suspected, but during the course of this examination the lungs were found to be abnormal. The patients in both groups were all hospital patients.

First Group.—I described three cases in the paper presented to this Association at the last meeting, which were sufficiently typical of the first group, namely, that with slight physical signs, in which the X-ray examination was of assistance. I will cite here five more such cases to add to the evidence brought before you at that time.

CASE I.—Michael H., aged thirty-six years. Entered March 7, 1898, with acute articular rheumatism, which began five weeks before entrance, with swelling in the knee, which extended to one hip, then to the other, then to the left ankle. Ten days before entrance both hands became red, swollen, and painful; five days before started again in the knee, right hip, right hand and shoulder. Physical examination of the lungs showed good resonance and respiration throughout. On March 10th the left wrist was red and painful. On March 18th this condition improved under salicylates. Practically well.

March 8th. X-ray Examination.—This was made to determine the size of the heart, as I was then making X-ray examinations of this organ in all cases of acute rheumatism. The apex of the right lung was found to be shaded as compared with the left lung; excursion of the diaphragm on the right side two and one-quarter inches; on the left side three and one quarter inches.

After this examination auscultation and percussion showed slight dulness on the right side from the apex to the second rib; tactile fremitus was increased, expiration prolonged.

14th. Second X-ray examination pointed to the right lung as the seat of the trouble, as before.

One milligram of tuberculin given, later two milligrams given, finally four given. Patient reacted to this last dose. Discharged April 7, 1898.

In May, 1899, he returned to the out-patient department, and Dr. Bartol kindly reported to me that he found no physical signs in the lungs.

The following case is inserted because I was able to watch its progress as it ran nearly the whole of its very acute course in four months, and largely in my service. It, as well as the other cases that I have seen, shows that in acute tuberculosis we may be warned of the rapid progress of the disease by making two or three X ray examinations at intervals of a week or so, and thus have another means of recognizing the serious character of the attack.

CASE II.—Sarah H., aged twenty-three years. Entered the Boston City Hospital, April 20, 1896, with acute articular rheumatism, first in the right ankle, then in the left ankle and right elbow. She had had cough, with bloody expectoration, for two weeks. The respiration and resonance in both lungs were good throughout. Heart by percussion seemed enlarged to the right.

On April 24th an *X-ray examination* was made to determine the size of the heart. This showed that the heart was not enlarged to the right, but there were signs of tuberculosis on the left side, namely, the left apex was shaded and the excursion of the diaphragm on

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

[2] The static machine which I now use for X-ray examinations has four revolving plates six feet in diameter and four fixed plates six feet four inches in diameter.

[3] In this paper I have presented more fully questions which I first brought out at medical meetings in 1896 and published in the *Medical and Surgical Reports of the Boston City Hospital*, January, 1897.

the left side was two inches, while on the right side the apex was clear and the excursion of the diaphragm was two and five-eighths inches.

Physical examination, after X-ray examination, showed many cracking râles over lower part of left front and axilla.

On May 6th nearly the whole of the left lung was shaded, and the excursion of the diaphragm was shortened by one-half an inch and moved one and one-half inches only. The apex of the right lung was now also darker than normal, and the excursion of the diaphragm was two and one-eighth inches. On May 12th the left lung was still darker than it had been, and the excursion of the diaphragm was reduced to one inch. Patient up and about. On May 17th the excursion of the diaphragm was reduced still further, namely, to one-half inch on the left side and to one and one-half inches on the right side.

The appearances seen in the X-ray examination were confirmed by finding tubercle bacilli. Patient died in July, 1898.

Case III.—Tofilus K., aged thirty-five years. Entered the hospital, January 11, 1899, with acute articular rheumatism. Physical examination: Increase of vocal resonance and fremitus, and marked whispered bronchophony in the right apex behind to an inch below the spine of the scapula. Over this area respiration was roughened and expiration much prolonged, but there were no râles and no dulness.

X-ray examination was made in order to determine the size of the heart. Upper half of the right lung was shaded; excursion of the diaphragm on this side one and one-half inches; on left side two inches. Tuberculin was given; reaction. Temperature 102° F.

Case IV.—Dennis H. F., aged twenty-eight years, entered the hospital, September 6, 1898, with malaria. While in the hospital he had some cough and bloody expectoration. Physical examination: Fremitus increased over the whole of the right side, especially at the apex; voice sounds also more marked on right side; no râles heard anywhere. No tubercle bacilli found in the sputa

X-ray Examination.—Left side less clear than right. Excursion of the diaphragm on the left side five-eights of an inch, on the right side one and five-eighths inches. Three milligrams of tuberculin were given after the temperature had been running from normal to 99° F. for some time. Temperature rose in eighteen hours to 103° F.

Case V.—Sadie McD., aged twenty-four years. Entered the hospital, April 6, 1898. Question of typhoid fever; temperature varied from 100° to 104° F. Was irregular. Physical examination of the lungs at entrance: Resonance somewhat diminished over fronts of both chests below clavicles; otherwise good. Respiration good throughout. Widal's test negative.

X-ray examination showed a well-marked shading on the left side as compared with the right. Excursion of diaphragm on the left side one and three-quarters inches; on the right two and one-eighth inches. After the X-ray examination had been made the chest was again percussed, and it was thought that the percussion note on the left side was less resonant than on the right side. One-half milligram of tuberculin was given, then 1 milligram, then 3 milligrams; reaction.

It will be noticed that three patients in this group had acute articular rheumatism. I have been struck with the frequent association of rheumatism and tuberculosis in these and other similar cases.

Second Group (four patients), namely, those without physical signs, that is, whose lungs were normal by auscultation and percussion.

Case I.—Mary C., aged twenty-five years. Hysteria. Said she vomited about a quart of blood about three days before and again that morning. Did not raise any blood while she was in the hospital. March 20th, physical examination of lungs: Resonance and respiration good.

April 1st, X-ray Examination.—Excursion of the diaphragm on the right side two and one-quarter inches. On the left side three and one-quarter inches. Three subsequent X-ray examinations showed a shortened excursion on the right side. Patient reacted to tuberculin. Temperature 105° F.

Case II.—Bertha M., aged twenty years. February 18, 1899, physical examination of lungs: Resonance and respiration good.

Two *X-ray examinations* showed a darkened apex and a shortened excursion of the diaphragm on the right side. Patient reacted to 10 milligrams of tuberculin. Temperature 101.2° F.; malaise.

Case III.—Julia D., aged twenty years, entered the hospital, March 13, 1899, for what was thought might be typhoid fever. No loss in weight. Unusually well-nourished and well-developed. Physical examination of the lungs showed resonance good throughout, respiration clear and distinct.

X-ray Examination.—Right apex to about the third rib shaded. Excursion of the diaphragm on the right side one and five-eighths inches, on the left side two and three-quarters inches. March 25th, 5 milligrams of tuberculin were given; reaction. Temperature 103° F.

April 14th.—Jerky respiration on the right, but nothing that can be considered abnormal.

Case IV.—Joseph M., aged nineteen years, entered the hospital, February 6, 1897. Physical examination of the lungs showed good resonance and respiration throughout.

March 12th an *X-ray examination* was made in order to examine the heart. Right lung darker from the apex to the third rib. Excursion of the diaphragm two inches on the right side, two and one-half on the left side. No signs by auscultation and percussion at this time.

21st. Second X-ray Examination.—Whole of the right side darker than the left. Diaphragm seen only in full inspiration on the right side; excursion on the left side two and one-half inches.

April 19th.—Physical examination: Some dulness of upper part of the right chest. Respiration diminished. No râles. Vocal and tactile fremitus very slightly increased. Resonance and respiration good over the left chest, both front and back.

25th.—Physical examination the same as on April 19th.

27th. Third X-ray Examination.—Right side darker than normal throughout, and on the left side darker from the apex to the upper border of the fourth rib. Excursion of diaphragm not seen on the right side; on the left side it was one and three-quarter inches.

27th.—Physical examination: No signs on the left side at this time by auscultation and percussion.

Patient died on June 4th. No tubercle bacilli were found at any time, though frequent examinations were made, but on April 13th he reacted strongly to 5 milligrams of tuberculin; marked malaise; temperature 101.5° F.

We see in this second group (of four cases), as well as in similar cases which I have presented elsewhere, that the X-ray examination gave warning of tuberculosis before any departure from the normal was obtained by auscultation and percussion. Let me indicate one or two reasons why we may thus detect increase in density in cases where it is not found by auscultation and percussion. First, if the density is much below the surface of the lung, as in central pneumonia, its presence is not recognized by auscultation and percussion, but a shadow of the consolidated portion of the lung is cast on the fluorescent screen as surely as if the pneumonic process were near the surface. This I have observed in several cases. Second, judging from the tests described below, made at the hospital in 1896 with lungs taken from post-mortem examinations, a shadow may be thrown on the fluorescent screen by a slighter degree of congestion than might be detected by auscultation and percussion. For these two reasons the X-ray examination may be the more delicate test under some conditions.

Tests.—Two feet above a Crookes tube I placed a piece of cardboard on which I set a thin, vulcanite cup—both the cardboard and the vulcanite offered little resistance to the rays—and beside the cup a piece of pneumonic lung, two inches thick (dense enough to sink in water), and while looking at the shadow of the lung on the fluorescent screen, which was held above the cup and the lung, I poured water into the cup until its shadow corresponded in darkness to that of the lung. I then measured the depth of the water in the cup, and found it was 2¼ inches. Further experiments showed that a much congested lung, 1 inch thick, which did not sink in water, corresponded in its shadow to 1 inch of water in the cup; also that a normal lung blown up to about the distention of full inspiration corresponded, where it was *3 inches thick*, to only ¼ of an inch of water. In other words, a lung in pneumonia or tuberculosis will, if sufficiently diseased, offer several times as much resistance to the X-rays as the same thickness of a healthy lung—that is, a very dense lung in either pneumonia or tuberculosis offers about as much resistance to the rays as the liver, and a much congested lung offers several times as much as a healthy one. One lung which I examined was normal except for a small, red nodule, less than ½ an inch in diameter. When this lung was looked at under the fluorescent screen this nodule was seen as a dark spot on a bright ground, the whole thickness of the lung casting less shadow than the small, dense substance. These experiments show that congestion increases the opacity of the lungs to the rays, and certain amounts of it, or of edema, even if there is no other pathological process, may sufficiently increase their density to cast a shadow on the fluorescent screen, and yet perhaps not increase it enough to give marked signs by auscultation and percussion.

Further, the lungs are brighter in full inspiration than during expiration. If a pasteboard box containing water, one-half an inch deep, be held over the chest of a large, healthy man, its shadow may be seen in inspiration but not in expiration.

It is perhaps best to repeat again the statement that the diagnosis of tuberculosis is not made by an X-ray examination alone, but it does give early warning in some cases of a departure from the normal in the lung which puts us on our guard and enables us, in conjunction with the history, etc., to make the diagnosis of tuberculosis, and thus in many early cases to arrest its progress by proper care.

The following case is suggestive:

C. B., a young man, whose father died of tuberculosis, was brought to me for an X-ray examination and for consultation. He had a history of recent rapid loss of flesh, but there were no physical signs, no temperature, no cough, and the pulse was not rapid. Both his physicians suspected tuberculosis, and he was being kept under observation until more definite signs should develop. The X-ray examination showed a darkened apex of one lung and a much shortened excursion of the diaphragm on the same side. My advice was that he should be sent directly where he could have good food and lead an out-of-door life for some months. This advice was followed. Four months later his family reported him better than he had ever been at any time in his life.

I believe that we may regard the successful care of early tuberculosis as dependent largely upon maintaining the condition and well-being of the patient at as high a point as possible.

The X-ray examination is also useful from another point of view. Physical signs of increased density at the apex and râles, if not confirmed by an X-ray examination, may be questioned in cases where the history and other evidence do not bear out these signs. I have seen seven cases where an X-ray examination prevented my taking too unfavorable a view, though the physical signs indicated beginning tuberculosis. In none of these has tuberculosis developed, and in such of them as I could test with tuberculin there was no reaction.

In doubtful cases two X-ray examinations should always be made at an interval of some days, in order that the second examination may verify or disprove the first, as there are various conditions, that I have referred to elsewhere, which may temporarily give signs similar to those observed in pulmonary tuberculosis.

In studying tuberculosis by the X-rays we usually find that the apex is darkened and the excursion of the diaphragm is shortened;[1] but we may find now and then only a general diminution in the clearness of the outlines of the lungs and of the ribs. This latter condition is found probably in cases where the disease is disseminated, but it is not easy to recognize this slight departure from the normal unless the physician is in constant practice with the fluoroscope.

Acute miliary tuberculosis sometimes offers difficulties in diagnosis, and is confounded with some other disease, typhoid fever, for example. An X ray examination of the lungs, by showing a marked shadow on the screen, though at the same time these organs are hyper-resonant to percussion, may direct the physician to a correct diagnosis. I examined with the X-rays a lung taken from a patient who had died of miliary tuberculosis, and found that where it was two inches thick it cast a shadow on the screen as dark as that made by water 1¼ inches deep in an aluminum cup.

I have seen two patients about again whom I had thought had miliary tuberculosis. The fluoroscope showed dark areas in their lungs, and they reacted strongly to tuberculin. They were too weak to feed themselves and feeble beyond any probable hope of recovery, but their health improved, and with it the appearances on the screen as shown by several examinations.

Other Uses Which Deserve Brief Mention.—The X-ray examination enables the physician to recognize some *old* or *latent areas* of tuberculosis which might otherwise be overlooked. In some of my patients I have found well-marked evidence of former disease by means of the X-rays, and on inquiry have learned that the original trouble dated back in some cases twenty or thirty years, and in others over forty years. The recognition of old areas of tuberculosis by the physician enables him to guard his patient against the dangers of lighting up the disease afresh.

Tuberculosis and Pleurisy with Effusion.—I have seen some cases of pleurisy with effusion in which the X-ray examination gave evidence of increased density at the apex of one lung, although this was not then detected by physical signs. The testimony of the fluorescent screen was confirmed by the finding of tubercle bacilli or by the tuberculin-test.

Tuberculosis with Bronchitis.—Here X-ray examinations may be of much service. In several cases of bronchitis I found by an X ray examination an increased density at the apex of one lung, which had escaped notice by physical signs. In nearly all of these cases tubercle bacilli were found later.

Tuberculosis with Emphysema. — The increased density in the lung due to tuberculosis may be so obscured by emphysema that it is not recognized by physical signs, but this emphysematous condition offers no obstacle to the X-ray examination; and the presence of tuberculosis in some of the cases of this class that I examined was confirmed by the finding of tubercle bacilli or by the tuberculin-test. The helpfulness of the X-ray examination where tuberculosis and emphysema are both present is twofold. It not only enables us to recognize tuberculosis where, by physical signs, it is undetected, but also to make a diagnosis of *emphysema* which had previously not been suspected by physical signs on account of the *tuberculosis* from which the patient was suffering.

To sum up: *Incipient Pulmonary Tuberculosis.*—I have seen thus far twenty-four cases, where there were slight or no physical signs, in which X-ray examinations showed signs of pulmonary tuberculosis. In all of these cases the X-ray examination was confirmed by finding the tubercle bacilli or by the tuberculin-test. In twenty-two cases I have made the diagnosis of incipient pulmonary tuberculosis in conjunction with other indications of tuberculosis, such as one or more of the following: Hemoptysis, loss of flesh, morning cough, night-sweats, evening rise in temperature, slight physical signs. In these cases the diagnosis was not confirmed by finding the tubercle bacilli, and the tuberculin-test was not used.

I recall two cases of pulmonary tuberculosis in which I found no constant signs by X-ray examinations, though there were râles, and bacilli had been found.

[1] The shortened excursion of the diaphragm may be due to changes in the lung itself or to pleuritic adhesions which prevent the lung from expanding.

I have recognized by means of the X-ray examinations tuberculosis with emphysema in nine cases, tuberculosis with bronchitis in eight cases, and tuberculosis with pleurisy in thirteen cases. In most, though not in all, of these thirty cases the diagnosis was confirmed by finding the tubercle bacilli or by the tuberculin test.

The traces of old tubercular lesions which were quiescent were apparent to me in a number of cases by means of the X-ray examinations.

I have been assisted by the X-rays to a correct diagnosis in three cases of acute miliary tuberculosis.

In the majority of the remaining cases of tuberculosis in which both a physical and an X-ray examination were made the latter indicated more extensive disease than did auscultation and percussion. Sometimes only one lung was suspected by auscultation and percussion when an X-ray examination showed signs in both lungs.

The reports of the Board of Health of the State of Massachusetts, as pointed out by Dr. Abbott, show that out of 1000 persons dying in this State between twenty and thirty years old 597 die of tuberculosis of the lungs. This fact indicates the importance of careful X ray examinations of persons between these ages and younger who may have any predisposition to this disease or in whom it may be suspected.

I think it will be useful to compare briefly two methods of making X-ray examinations in diseases of the chest, namely, the one by the fluorescent screen and the other by the X-ray photographs, and the description of a case is a simple way to present the subject.

C. P., aged six years, entered the Boston City Hospital, March 16, 1899, with croupous pneumonia. Illness began on March 13th. Physical signs at entrance were as follows: Resonance and respiration good everywhere, except over a small patch in the left back, from the mid-scapula to the lower angle, where there were bronchial breathing and bronchophony.

March 17th, X-ray examination by the fluorescent screen showed a darkened area, 2¾ inches wide, extending outward and upward from the left border of the heart. The excursion of the diaphragm on the left side was ¼ of an inch; on the right side 1 inch.

31st. There were no physical signs and there had been none for four days. *A second X-ray examination* showed much improvement, but the dark area was still readily perceived, though it was not so dark as on March 17th. The excursion of the diaphragm on the left side was 1 inch, on the right 1⅜ inches.

As on March 31st and the four days previous, there were no physical signs in the lungs of this patient, although the signs of departure from the normal were very patent on the fluorescent screen, the case seemed to me a favorable one in which to make a comparison between the signs of consolidation as recognized on the one hand by the screen, and on the other by X-ray photographs.

Three negatives were made (to see if variation in the time of exposure, or if tubes with different vacuums would bring out anything), one on March 30th and two on March 31st. On March 30th the exposure was four minutes; on March 31st, three minutes, and a second negative, with an exposure of two minutes, was taken with a different tube on this same day (the tube was in all cases three feet away). From these negatives I had prints made, and *in none* of them did I find evidence of increased density in the left lung as compared with the right.

CASE II.—E. L., a woman, aged eighteen years, entered the hospital February 28th. She had pneumonia involving the lower lobe on the left side, which began one week before entrance, February 21st. There was nothing unusual about the progress of the disease. Four X-ray examinations were made, March 1st, 11th, 23d, and 30th, respectively. Neither on March 20th nor afterward were there physical signs on auscultation and percussion; resonance and respiration were good throughout; but I found signs of consolidation by the fluorescent screen, as indicated by a darkened area and shortened excursion of the diaphragm when compared with the right side. An X-ray photograph taken at this time did not indicate disease, and there were no physical signs.

To sum up: On March 30th in neither of these patients were there physical signs, nor did X-ray photographs taken on this day give any indication of an abnormal condition of the lung, but well-marked signs were seen on the fluorescent screen.

Again, in two cases of incipient tuberculosis in young women in whom the disease was recognized first by an X ray examination with the fluorescent screen I could see no difference in the two sides by the X-ray photograph. In one of these patients I found no physical signs at the time the X-ray photographs were taken; in the other, where the X ray photograph was taken some time after the disease was recognized on the screen and the disease had progressed, there was slight increase in tactile fremitus and a prolonged expiration on the right side.

The cases above mentioned lead me to believe that in these diseases we may have in the fluorescent screen a more ready, convenient, and delicate method of recognizing an abnormal condition of the lung than we have in X ray photographs, and the screen has the advantage of revealing the mobility of the diaphragm and heart.

If simple precautions are taken there is not the slightest *risk* even of an X ray burn. I have examined about 3000 patients without a single case of injury or of inconvenience even.

I wish to emphasize the fact that signs may be obtained by an X-ray examination when the disease is limited not only to one side, but is just beginning even on that side, before there are physical signs in the first lung or cough.

It is interesting to note that X-ray examinations show that the disease begins oftener in the right than in the left apex.

In conclusion, I desire again to urge the adoption of a method which aids in the early detection of pulmonary tuberculosis. First, because an early diagnosis gives the best opportunity to arrest the disease; and second, because patients may then be taught early simple precautions which will prevent them from being a source of contagion to others should cough and expectoration develop.

I desire to record again my appreciation of the value of Dr. William H. Rollin's investigations, published in the *Electrical Review*, which have promoted the usefulness of the Röntgen light in medicine and in surgery, and to express my gratitude to him for his untiring readiness to aid me to overcome the obstacles which have beset those who are using X-ray apparatus.

CLIMATE AND RENAL DISEASES.[1]

By J. B. WALKER, M.D.,
OF PHILADELPHIA.

At a meeting of this Association, held in 1888, Dr. J. C. Wilson read a paper on "Climate and Bright's Disease," presenting the views held by the leaders of thought in diseases of the kidneys; and more recently Dr. Solly, in his admirable work on "Medical Climatology," has given a comprehensive epitome of the same subject as viewed by himself and the various authorities of the day. There remains perhaps but little to be added as regards the general aspects of the question except to verify, modify, or correct the conclusions already arrived at and to specialize and individualize as observation and experience suggest.

The causal relation of certain climatic conditions for and against affections of the kidneys has been sufficiently established. Their prevalence in temperate climes where variability of temperature is accompanied by moisture, as is found in the inland portions of the Atlantic watershed in our own country, compared with their infrequency in torrid regions is affirmed by all authorities and abundantly supported by statistics; and while all admit that the habits and modes of life of the inhabitants of the former have something, no doubt much, to do with this state of affairs, yet that the climatic conditions *per se*, bear a direct causal relation in precipitating such attacks is thoroughly appreciated.

The conditions of climate acting in this causal manner are variability of temperature associated with dampness. The dampness is not alone represented by the amount of moisture contained in the atmosphere, but what I believe to be of much more vital importance, the dampness of the soil. As our immortal Bowditch pointed out long ago that it is of prime importance in choosing a climate for phthisical patients to also select a dry, porous soil, and *per contra*, that a damp soil is an important factor in inducing or favoring the development of phthisis, so I have no doubt the climatic factor of prime importance in inducing renal disease is dampness of the soil. Next to the respiratory, no system suffers from improper climatic conditions so seriously as the renal. Tucked away though these organs be in the warmest and most protected portion of the animal economy, yet through the workings of the vasomotor apparatus climatic variations directly impress them. If, as is frequently the case and increasingly so with advancing years, they are in a condition of engorgement due to their efforts at elimination of an excess of or an imperfectly metabolized tissue waste, or from other irritating ingredients of the blood as alcohol, lead, etc., if, while in this state, the skin insufficiently protected be subject to cold and especially damp cold the transformation into an inflammatory state is easily made. If this is repeated year in and year out pathological changes must of necessity result and more or less crippled kidneys be the outcome. It is for such crippled kidneys that climate furnishes the most relief. They do their work under favorable conditions well but quickly show their imperfections if unfavorable conditions arise. Such kidneys secrete an abundant urine of low specific gravity, ranging about 1010, without albumin, usually acid in reaction, and sometimes precipitating the urates on cooling. If the possessor of such a pair of kidneys has an attack of acute disease he is apt to present an albuminous urine with casts, and life may be in jeopardy or, as is more frequently the result, renal inadequacy is exaggerated by an increase of the crippling process.

It is in this class of cases that variability of temperature may exert the same deteriorating influence, in some cases inducing an attack of acute Bright's disease, but in a vastly larger number stopping short of this, giving an albuminous urine, not smoky nor possessed of blood-casts, but often associated with evidences of imperfect depuration of the blood. Among these evidences are headache, usually occipital, anorexia, running into nausea and occasionally vomiting and sometimes slight vertigo. These

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

symptoms are present on awakening in the morning and sometimes wake the patient two or three hours before his accustomed time. They may shade away before or immediately after breakfast, are always absent or greatly diminished by 11 A.M., sometimes to return about 4 P.M., not quite so severe as in the morning and absent entirely by bedtime in all but the severest cases. For this class of patients a proper climate will do much to restore the renal equilibrium. Such individuals are usually in perfect health during the summer months when the skin is active and an out-of door life possible, but with the onset of the cold and dampness of early fall the symptoms return each year with perhaps increasing vigor unless recognized and the condition carefully treated. Often in spite of the utmost precaution the kidney changes become more and more marked.

During the winter of 1898–1899 a large number of such patients came under my observation. The extreme variability which marked our Eastern coast climate from early in September, through the winter and until the middle of April, with rain or snowfall at short intervals, the air constantly saturated with moisture and at least in the cities the streets continuously wet, the number of respiratory diseases was vastly increased and the number of embarrassed kidneys greatly multiplied. In some subjects the kidney embarrassment accompanied the catarrhs of the air-passages, modifying their course and retarding the convalescence. In others it existed alone. It was usually easily controlled and disappeared in a few weeks; in other instances it developed into acute catarrhal nephritis. So much for the causal relations of climate.

As for the remedial or therapeutic value I will point first to the improvement of this class in the warmer, drier summer months in the same latitude and locality. The modified diet of the summer with its diminished meats, and increased vegetables and fruits no doubt plays no unimportant part in this improvement; but when this feature is persisted in after the inclemencies of the winter appear and systematic exercise, scrupulous attention to the skin and bowels and other hygienic matters have been most carefully persisted in and yet in spite of this the one factor of climatic changes overtops all and reproduces the former condition, one is forced to attribute not a little but the most of the summer's improvement to the climatic conditions associated therewith.

In those cases in which attention to diet, skin and bowels, systematic exercises, etc., with such medicinal aid as may seem wise, fail to prevent attacks of renal incompetency during the winter season I have found a sojourn at Lakewood or Atlantic City of vast benefit. Here the sandy soil dries quickly after a storm, snow soon disappears, and both soil and air are constantly drier except during the actual rainfall. The appetite is usually rapidly restored as the nausea disappears, the headache vanishes, sleep is undisturbed, and in a vew days the change is almost marvelous. The kidneys have resumed their equilibrium and all the functions feel the impress. This experience, coinciding with one's preconceived notions and repeated in a number of cases leads me to present this very imperfect paper.

In conclusion, I would state that as dampness of soil is perhaps the most objectionable climatic factor in the induction and aggravation of crippled kidneys, for those residing where this factor prevails and for crippled kidneys in general the sunny, sandy seashore resorts, especially where dryness of air and sunshine are associated with a suitable soil, furnish an aid to relief of unquestioned value.

There is no occasion in most of these instances to send such invalids to far distant points in search of a suitable climate. In the inland cities of our Atlantic watershed, and even in those cities near the coast where an impermeable pavement aggravates or perpetuates the dampness, the dry, sandy seaside resorts to be found near at hand from New Jersey to Florida, where comfortable living is possible and where patients can take their out-of-door exercise dry shod, furnish an easy, ready and hence available aid to embarrassments of the renal functions which constitute the vast majority of renal diseases met with, and which would otherwise drag their weary length along until the warmer and drier climate of early summer brings relief, while all the time histological changes are possibly carrying the crippling to the danger limit.

I have no desire to detract from the great advantages of the drier and continuous warmth of the great Southwest for the more marked cases, nor of the Hot Springs of Virginia and Richfield to bring recalcitrant kidneys back to their normal equipose. For severer cases these may be requisite. My wish is to give my experience as to the value of more accessible places which supply the requisite aid in many cases when the renal changes are still within the possibility of harmonious work under favorable conditions.

A NEW OPERATION FOR INGUINAL HERNIA.[1]

By CARL BECK, M.D.,
OF NEW YORK.

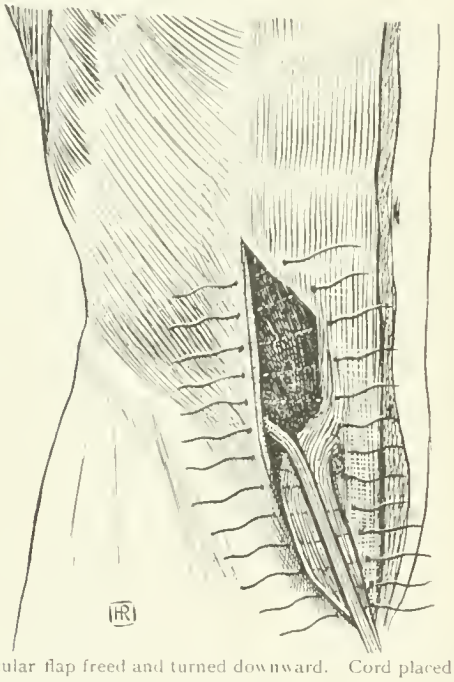
THE results obtained by Bassini's well-known method are so brilliant that it may seem arrogant to make any claims for new methods. Still, as Bas-

[1] Read before the Surgical Section of the New York Academy of Medicine, March 13, 1899.

sini himself admits that he had recurrences in three per cent. of his cases and other surgeons even more, it is legitimate to look for further means of fortifying the abdominal wall. Eleven days ago I tried to accomplish this in the case of a patient upon whom I had previously performed Bassini's operation, and who had presented himself with a recurrence. The modus operandi is as follows:

The incision is made down to the internal surface of Poupart's ligament alongside the outer margin of the rectus muscle, exposing its lower third down to the shelving portion of Poupart's ligament. The sac is isolated from the cord, and ligated and cut off within the internal ring While the cord is held away the cut aponeuroses are dissected backward and an oblique incision is made which divides the lateral fibers of the rectus muscle transversely to the extent of about one third of its width, a little below the lower third of the muscle (Fig. 1). The

Fig. 1.

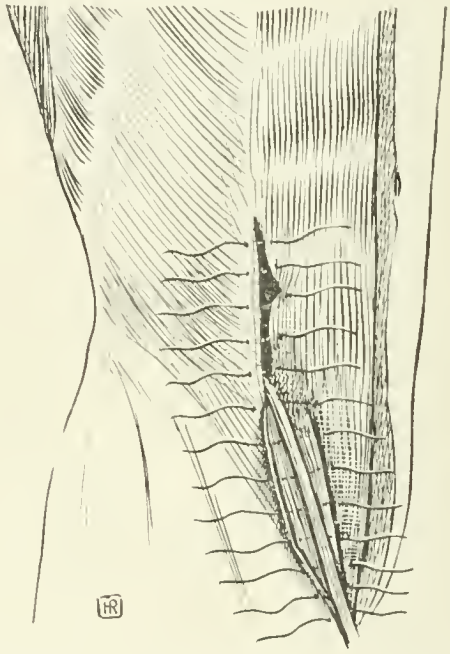


Muscular flap freed and turned downward. Cord placed above flap.

incised fibers are then so far severed from the remainder of the muscle that their upper portion when turned downward will reach Poupart's ligament without any considerable tension. This turned flap is now fastened to the conjoined tendon at one side, and to Poupart's ligament on the other, with formalin catgut after the cord has been placed upon it so that the cord rides, as it were, on the muscular flap. The gap caused by the resection of the flap is now covered by uniting the outer margin of the rectus muscle with the broad abdominal muscles. Then the cut aponeuroses are united above the cord by a continuous suture, thus forming a very strong posterior *muscular* wall, which in large and direct hernias may be of importance (Fig. 2). It may also be that the removal of the sac may thus be rendered unnecessary in small hernias.

The patient showed no reaction after the operation, and the result seems to be perfect. I have performed the same operation twice since; once on

Fig. 2.



Flap held by sutures at Poupart's ligament as well as at the conjoined tendon. Gap caused by the elimination of muscular portion united.

a boy eight years of age, and once on a girl of six years. Thus far in both cases the result has proved to be satisfactory. The real value of this method, however, can only become evident after more experience and observation. The question of the gap as well as that of the division of the nerves and of cutting off of some of the blood-supply has been well considered, and the objections seem to be only theoretical.

CONCERNING COLORADO.

By SAMUAL A. FISK, A.M., M.D.,
of Denver, Col.

It is a popular phrase in Colorado that one has come West either for health or wealth, and in the popular mind there are two classes in the community, the health-seeker and the wealth-seeker. Experience has ample justification for the existence of each. On the last day of the old year I met casually on the streets of Denver a man in robust health and

in active business life who came there from an Eastern city some seven years ago on account of some pulmonary complication. Since that time he has had many a strain, financial and from illness, and yet has weathered them all and to-day is a member of one of our leading mercantile houses and has taken out a life insurance policy in a representative company after a rigid examination and with a full knowledge on the part of the examiner. He stands as a type. What is true of him can be said of thousands in Colorado. Not that they have all taken out life insurance, but because from an almost certain death they have secured a restoration of heath so that they are well in the sense that Dr. Williams uses the terms, *i.e.*, they are able to follow their occupation without any recurrence of their former symptoms.

This is a simple statement on paper but it is of tremendous importance to the individual and to the masses. Pulmonary tuberculosis is the great foe of mankind. At the present day one so afflicted is regarded with suspicion, almost as though he were a leper. "On no account whatever must you ever enter my house again; you are a source of danger to everybody," writes one. This is a panicky fear, it may be, for which the medical profession may be somewhat responsible, but warranted perhaps by the appalling annual mortality from pulmonary tuberculosis, which causes fully twelve per cent. of all deaths, and is estimated to have killed at least 133,000 persons in the United States during the year 1894. So far injections of various sorts and medicinal remedies have not proved of avail in treating this disease, and we have to come back to the lesson taught by the man whom I have cited, that of "climatic cure." Quotations from eminent authorities on which to ground this belief abound but one from Sir Andrew Clark will answer the purpose: "I am as sure as I can be," he writes, "that recoveries from phthisis, judiciously treated at high altitudes, are much more numerous and much more lasting than those treated by any other method at any other place." And Dr. Herman Weber adds, after speaking of European stations: "More important to us in the treatment of phthisis are the health-resorts of America. . . . In the Rocky Mountains of the United States we possess indeed an endless variety of mountain climates." Since these remarks were made Dr. Solly has given figures which, taken from a large range of observers, amply confirm what these writers say. His data show "improvement" in 59 per cent. of all cases treated in low climates (ocean, island, coast, inland sanitariums, and desert), and in 76 per cent. of those treated in high climates, from which he draws the conclusion: "This inquiry has clearly demonstrated two things, *viz.*, that the majority of consumptives do better, other things being equal, the further they are removed from the sea, and that they do better in high than in low altitudes." But one naturally asks, "Why go to the mountains? are not cures brought about in New York City and in Boston? Are not Abana and Pharpar better than all the waters of Isreal? Assuredly recoveries have occurred and do occur right on the seacoast, but in such a serious matter one cannot afford to trifle. The best is none too good. If the house is on fire one does not fool with it or wait for the flames to become more extensive before setting to work to put out the fire, and that in the best way at his command. Why should one take risks with his health that he will not take with his house?

What, then, are the advantages of the high altitudes of the Rocky Mountains of Colorado in the treatment of pulmonary tuberculosis? There has been a great deal of theorizing on this point, good, bad, and indifferent, substantiated and unsubstantiated; but what is wanted is plain, everyday experience. In reading all that has been said on the subject, one is often reminded of

> If this young man expresses himself in terms too deep for me,
> Why what a very singularly deep young man this deep young man must be!

The questions of free ozone with its insufficient evidence of terrestrial electricity and the necessity for it to pass properly over the system; of the influence of diminished atmospheric pressure in causing deeper inspirations and so bringing into play heretofore unused and diseased portions of the lung, the writer does not profess to know much about. He remembers that experience has not always borne out conclusions supposed to be established as facts, and that even if Tyndall did state that spontaneous generation did not occur at the height of the Bel Alp (7000 feet), and even if Miquel did count the number of bacteria in ten cubic meters of air at various heights, from that of the Rue de Rivoli up to 2000 or 4000 meters, where he found none, nevertheless we must not infer that altitude *per se* produces asepsis, as we know that wherever large numbers of human beings congregate there the purity of the air is liable to be impaired. He also recalls that experiments have shown that Koch's results with reference to the effects of sunshine upon the bacillus tuberculosis are not to be universally applied. Bearing these things in mind he thinks that it is wise not to be too hasty in our conclusions on matters of opinion or of theory. One thing is patent, as Solly has shown; more patients do well in high altitudes than in low. There is something in the location that improves the powers of repair of the human system, that at least increases the resistance of the body to the rav-

ages of the disease. Altitude seems to be a factor. In Colorado the so called "invalid belt" varies from 4600 to 8000 feet. Then there are the many climatic conditions which conduce to an out of-door life, which in itself leads to repair. For instance, the air is remarkably dry, and in a dry air the sensations of heat and cold are less intense; the amount of rain- and snow-fall is slight in comparison with that which prevails along the Atlantic coast; by reason of it Denver ranks as a cool, stimulating climate; the daily motion of air (wind) is much less than prevails in our large cities, from which many of our patients come, being 101 miles less than the daily average of Boston, 85 miles less than Chicago, 62 miles less than Philadelphia or New York; and above all there is almost unexcelled sunshine. The Weather Bureau's statistics on this point show for an average of ten years that Denver had only fifty-one cloudy days in a year. By the term cloudy is meant that the sky is from eight-tenths to completely obscured by clouds. This gives an average of 314 days in a year when the patient can be out of doors, and more than that, for many of the so-called cloudy days are days when a patient can comfortably be out. This is a state of almost perpetual sunshine; where one makes engagements without the proviso "if it does not rain;" where umbrellas are so seldom used that they get misplaced or lost.

From September to April, inclusive, in a year taken at haphazard, we find only 11 days that were completely cloudy, that is, 11 days out of 242 that were cloudy all day long so that an invalid would have to be housed. But one should regard the actual as well as the possible sunshine. Here the figures are still more striking, showing an average of 65 per cent. per annum as against 49 per cent. in Philadelphia. The statistics for November, 1898, give Denver a total of 77 per cent. of possible sunshine, and for December, 85 per cent. Moreover, the possibility is great, for the stretch of plains to the east and the distance of the mountains to the west from Denver allows the sun to shine on the city all day long. This gives a possible 9 hours 26 minutes of sunshine for Denver on the first day of January as compared with 4 hours 57 minutes at Davos Platz. I have heard the difference likened to that of an invalid getting out of bed in a room with and without a fire. In other words, with a sunrise at 7.20 instead of at 10.20 o'clock the air is warmed for the patient when he has had his breakfast and starts out.

We must not neglect to mention the character of the soil, which is sandy, gravelly and sloping. There are few surface streams. Many of the beds are dry arroyas, known as "sand creeks," and the snow from the mountains seems to pass away in underground currents. Artesian borings strike water almost anywhere. On the eastern slope the decline, and consequently the drainage, is gradual from that of Denver (5280 feet) to the Missouri River at Omaha (1100 feet).

"Some climates," says Weber, "are apt to produce a feeling of langor and diminished inclination for food, while others raise the nervous system, improve the appetite, digestion, sanguinification, and muscular energy, and facilitate the elimination of used-up matter," just as there are remedies, like morphin, which soothe but check the appetite and nutrition, and others, like the bitter tonics, which improve by stimulating. It is this bracing quality of the Colorado climate that is characteristic of it. The people of the State are essentially a buoyant race. They will not down. Every morning the bright sunshine brings renewed hope and vigor. As the man said, whom I met on the street, as already mentioned, "Isn't this stunning air?" It is hard to stay indoors. Former students and college men complain that Nature is too inviting.

But writers on Colorado have been accused of concealment, of a *suppressio veri*, not of misstatement. It is said, for instance, that nothing is mentioned about the winds. Colorado is classed in the popular mind with that large country "Out West" (somewhere, just where is indefinite), where they have blizzards and where persons are blown into eternity. Facts count for little. There is some error in the Weather Bureau's figures. It cannot be that there is so great a difference in favor of Denver, as against Boston, Philadelphia, and New York as the statistics show. Even the inhabitant of peaceful old Northampton will forget about its tornado which lifted a load of hay completely from the wagon and landed it in the street, tore the bridge across the Connecticut from its piers and dropped it in the river, to say nothing of having laid low more than one hundred of its majestic elms, when he talks about the frightful blizzards "Out West," and therefore, because west, in Colorado.

It is also said that Colorado has intolerable dust storms. These critics forget that a dry soil is one of the necessary accompaniments of her climatic conditions. To an air so dry that salt does not need to be dried in the oven; that shoes do not mould if left unworn; that polished steel will remain for years without rusting; that soda-fountains do not sweat in hot weather; nor collars wilt; that crimps stay in the hair, add a small precipitation, an intense and constant sunshine, and a naturally sandy soil—such conditions conduce, especially in the city, to the pulverizing of the soil, and a

slight wind, again more marked in the city where the streets act as a funnel, will pick it up and make the presence of the dust felt. The prevalence of the dust storm, like most things that are disagreeable, is overestimated and remembered, and given undue prominence. The Eastern woman will not forget that her skirts got dusty in March and April, instead of muddy, to which she has been accustomed, and her irritation never subsides. I do not mean to say that we do not have at times winds which send the dust flying and render being out unpleasant, but such times are few and far between as compared with the general run.

Again, it is said that Colorado does not have constant balmy weather and Italian skies. Who said that she does? Certainly not the well informed. It is not her fault if one goes there in midwinter with only summer clothes. This is by no means an exaggerated statement, but poor Colorado has to take the blame. While it is not an uncommon thing to sit with open doors and windows in the heart of January at midday, or to swing in the hammock, or to picnic; the climatic conditions, the rarefied air, etc., are such that the night (when the invalid should be indoors) may be intensely cold. Sometimes, too, the days are cold. One cannot pluck roses out of doors in midwinter in Colorado. The ground is covered with snow at times and there may be a few days of sleighing, but it does not last long and one is surprised on the plains to see this whiteness fade away without making the air moist or the ground damp. It is constantly being hurled in our teeth that So-and-So came to Colorado and did not improve, in fact, may have died. Such is undoubtedly the case. It is not every one who gets well, or who even improves. But the number of the latter would unquestionably increase were better management shown, especially in the selection of the individuals that should come. On this point there should be the best of medical advice. It is folly, if not cruelty, to send patients thousands of miles from home as a last resort when they would not gain anywhere. Then, too, many who do come so order their lives that it would be a miracle if they got well. I am sorry to say that many drink themselves to death. They are falsely impressed with the idea that whisky is a good thing for consumptives, and why not "gallons of it?" Others smoke themselves to death or live thoroughly unhygienic lives. How can one improve if he smokes all day and all night too? If he sits in a stuffy room filled with tobacco-smoke and plays poker when he should be asleep or in the fresh air? Yet such things are not infrequent. I imagine that one could drown even in Siloam if he were determined to do so. Still others under a false impression that exercise is the thing, overdo; they climb mountains, or ride horseback on the run, or puff at their wheels, or overwalk when they should be quietly basking in the sunlight, wrapped in rugs and thoroughly warmed. Still others freeze to death, not literally, but they have brought their summer clothes and are not prepared for a cool climate, and being of a low reaction at the best they cannot endure the rigors of the cold. Others, it may be, are insufficiently fed. It takes money to make the mare go in Colorado as well as elsewhere, and I am sorry to say many and many a poor unfortunate is landed at our doors like a baby in a basket, without any provision having been made for his maintenance afterward. Our hospitals are full of them, our sympathies go out to them, but they are always with us. We do what we can, but almost invariably with the same result. They do not have a fair show, and they go from bad to worse, physically, sometimes morally, and die.

Some years ago I heard a prominent physician say: "I have given up sending my patients to Colorado; they can't get anything to eat." He showed his inaccurate information by his statement. Good, nutritious food is to be had and plenty of it. It may not always be of the kind that one is accustomed to. One cannot expect a bluefish right out of the water 2000 miles from the ocean, but one can be on the coast of Maine and fare mighty badly on the fish question. The eminent gentleman before mentioned would be agreeably astonished at the excellence of the oysters, or clams, or halibut, or whitefish, or salmon, or cod, or even the broiled live lobster that could be put in front of him in Denver. It is needless to say that the meats are of the best, and as for the vegetables and fruits they cannot be surpassed. Flour, milk, butter, eggs, and such staples are to be had as good as anywhere in the world. Of course many people prefer their roasts done to death, and there are those in Colorado, as elsewhere, who still fry their beefsteaks.

But after making all allowances, the fact remains that the Colorado climate is mighty good, perhaps the best in the world, and that seventy-six per cent. (Solly) of all patients, good, bad, and indifferent, and eighty-nine per cent. of those in the first stage, that go there, are benefited. The climate is not adapted to every invalid. On that point there should be proper advice before going; nor does every patient do well after arrival. Climate of itself is not all. It needs wise use. On that question there should be suitable directions from men of experience on the spot.

Many persons feel the separation from accustomed friends and scenes and can find nothing good in

their new surroundings. The sun does not shine for such, nor is the glorious moonlight, as clear as crystal so that one can see to read print by it, anything but utter darkness to these. Some such are attacked with genuine homesickness, just as some, and not a few, die of it at the wars. Others cannot rise to the emergency. They prefer electric-light to sunshine, pavements to dry soil, clouds to blue sky. Their comparisons are drawn from artificial things. The rich coloring of the mountain side is likened to velvet; or a piece of lace is more wonderful than the columbine; the glide of a waltz is more graceful than the magnificent poise of an eagle; or the flight of a balloon on canvas more majestic more uplifting than the mountaintop. Others do not find God in Colorado, in the Rockies, as wonderful as across the seas, in the Engadine. For all such pity should be felt. "There is one glory of the sun and another glory of the moon, and another glory of the stars; for one star differeth from another star in glory." So there is the glory of the rocks and waves of the Maine coast, or of the miles upon miles of sands and beach of Cape Cod, or of the Presidential range of the White Mountains, with its "scratch on the face of Nature," or of the quiet peace of the Connecticut Valley, or of the Hudson, or of Lake George, or of the mighty torrent of Niagara, or of the Great Lakes. Each different from the other in glory, but each has its own crown. Who, then, shall deny to Colorado and to the Rockies their glory? It is unlike the others, but it is none the less good.

> Vain, all in vain, will outward sight be found,
> Unless the light of heart and mind abound.

If one will not be pleased with mountain scenery unless the tide comes rolling in, or if one must have the graceful elm and vistas and ha ha fence in every landscape he had better not come to Colorado; or if he can walk no other street than Fifth Avenue; or if his eyes reach no higher than the Waldorf Astoria he will find no pleasure in our mighty mountain sides. But if one is really fond of expanse, and loves the violet and the purple, he cannot find them to better advantage than on our plains. Barren plains they are, to one accustomed to the undulating meadow, but how grand! how immense! how roomy! Can one hear the gentle turtle-dove cooing to his mate at dusk without feeling at peace with the world? or see the ridge in deep blue outline, cameo-like, clear up against the sky without holding his breath in awe? or listen to the sighing of the pines, or even to the absolute stillness of Nature without having some chord touched and his heart reply:

> Hast thou named all the birds without a gun?
> Loved the wood-rose, and left it on its stalk?

Then walk with Carter of Breckenridge, or Wallihan of Ray, and learn to enjoy yourself; or revel in the columbine, the penstamen, or the mariposa lily and consult with Leida Lansing. What mean the mighty seams and upheavals? The tremendous cañons, the majestic mountains, the beds of prehistoric fossils? Ah, who can say?

But an overwhelming objection is raised by many that if one gets well in Colorado he is obliged to stay there. To many this seems insurmountable. They would rather die, they say, and they will probably have their way. "I *will* drown, and nobody *shall* save me," is their motto. There is no use wasting time on such. But there are others who think that they would find it an exile, and they make a mountain out of a mole heap. To most of mankind it holds true, as said of Job, "Yea, all that a man hath will he give for his life," and recognizing the danger they are not so particular about the means of escape. When pulmonary tuberculosis exists one cannot rationally doubt the danger, and Colorado is by no means a questionable boon, even if regarded simply as a means of escape. Add to its other advantages its connection with the world, its accessibility, the comfort and ease of reaching it, the luxury of one's surroundings after one has reached there, the progress of its civilization in all departments, educational, civil, and religious, and it is thoroughly unreasonable to call it an exile. Colorado does not possess all that an older civilization affords, but she is by no means cut off from the rest of the world. Patti, Melba, Nordica, Ysaye, Wilhelmj, Sarasate, D'Albert, Paderewski, Damrosch, Bernhardt, Modjeska, Booth, Barrett, Mansfield, the Kendalls, and many others have found it to their advantage to look in upon her, and they have not gone away empty. Denver is called the "Queen City of the Plains," a title which she wears nobly and with dignity.

However, one is not always obliged to live there. Most patients find it wise to do so, for they recognize that like causes will produce like results and they hesitate to go through life with the sword of Damocles hanging over their heads. Having been saved from drowning once they are loth to jump back into the water. As has already been said, there is many an example to prove that persons with a tubercular tendency do live and work in the East; but experience has also shown that such a course is invariably attended by risk, and mistake means such dire results that one may well think twice before taking the chance. Most persons feel that it is better to err on the safe side, especially when that side is so attractive.

Of the numerous instances of those who are cured

and are living at the East again, let me cite two from my own experience:

A young lady came to Colorado a few years ago practically bedridden, with regard to whose tubercular condition, as shown by physical and laboratory test, there was no doubt, after three years, during which time she spent one summer in the East, she left and went abroad. Some months later she was reported as following the hounds and playing hockey in a most energetic fashion with the English girls who did not seem a bit stronger than she; and a year after that she wrote from the coast of New England of yachting, swimming, golfing, playing tennis, riding a wheel, and added: "My health is perfect. I believe I am as strong as I used to be, which seems wonderful to me."

The other subject, a clergyman, in middle life and of great activity, spent four months in Colorado, having been sent West by a leading diagnostician of New York. There was no question as to his condition. His gain was amazing. His search for health was a matter of the purest business. There was no deviation from the straight line. He ate well, slept well, got hours of fresh air; he allowed nothing to interfere with measures he esteemed to be for his good. His restoration to health was a duty he owed to his family and to God. At the end of four months he returned to his parish and his work (some three years ago) where he has remained ever since, in the enjoyment of complete physical vigor. Other cases could be cited, but these will show what is possible.

Does one want to take a vacation? Where can more of diversity or of interest be found? Here are the bracing mountain air bringing distant objects near to, the clear blue sky, the day after day of sunshine, the dry soil, the freedom from moisture the exhilaration, the buoyancy. As one grows older it is charming to be the boy again, to get up in the morning glad to see the sun, refreshed by a night's sleep, with a heart for any fate, ready to throw up his hat as of old. Here, too, are to be found the inducements to vigorous, out-of-door life, from riding the broncho and "rounding-up" with the cowboys, to hunting the bear, or mountain-lion, the elk, antelope, or deer, or throwing the line, or decoying the duck. If one's inclination is more gentle, and he wants to be soothed and to bask rather than exercise vigorously, there is Manitou with its sparkling table-water, to many more palatable than Apollinaris; or Glenwood with its baths and pool, where one can swim as the writer has done, in an acre of water, naturally warmed, while the snow is falling all about and the fountain close at hand has frozen into a pyramid of ice as high as a house. And there are hosts of other springs, all of which have their value. Does one want scenery? There are the mountains with their lofty peaks, their deep gorges, their cañons, their snow-capped summits, their parks, their ever varied and novel aspect. They are the Rocky Mountains, different from the usual, with a nobility all their own. Says a recent writer, after tabulating a long list of the peaks bearing a name, "Seventy-two peaks between 13,500 and 14,300 feet in height are unnamed, and so not showing in this list." Any one of these peaks, now unnamed, would be a fitting jewel to any range.

One is led to speak of the mountain passes our railroads climb. The train takes but a few cars and two engines. It is no easy ascent. The incline is quite perceptible. The panting, fuming, snorting engines are to be seen on the curve. First they go north, and soon they go south. They twist and turn and describe a letter S. One can touch the rocks, close at hand, or on the other side look over a precipice so steep that he becomes dizzy and closes his eyes. As the pass is climbed a glorious expanse of summit after summit stretches before the gaze. It is beyond description. At last the engines stop their panting; the toil and strain is over. The summit (10,856 ft.) is reached. Surely there can be nothing but cloudland above! But, no! There, still reaching thousands of feet into the sky is Ouray, with majestic dignity, proclaiming that he is yet a mighty mountain. The effect beggers description, and with bated breath the descent is made. Pages upon pages could by no means exhaust the subject. One scarcely knows where to stop.

Says one of the "Cape Cod Folks" with unusual force, in speaking of his people and locality: "Thar's suthin' about it sorter holts to 'em. They allus come a-driftin' back in some shape or other." This is peculiarly true of Colorado. The place and the climate possess a fascination for one who has experienced it, and he is apt to come "a-driftin' back."

But, to return. Take it for granted that it is wise for the tubercular patient, who would have died had he not come to Colorado, to remain in Colorado. Assume that he is well and that he is content to let well enough alone. The State of Colorado will furnish an adequate vent for all of his energies. He can live in a climate adapted to his condition, and at the same time do his full work in life. And not the invalid alone, but any man will find an ample outlet for his most active efforts, for all of his energies. This is no fairy tale, but good, solid fact.

The area of Colorado is 103,925 square miles, nearly 2½ times that of the State of New York, or about 13 times that of the State of Massachusetts.

Colorado is not a one-resource State, not simply, nor principally, a silver-State, as many suppose. Her mountains teem with wealth; her plains and parks feed and shelter thousands of live stock; her valleys, under irrigation, reward the husbandman with cribs flowing over. At the present time the Klondike is the El Dorado. An importation of a few hundreds of thousands of gold from that region is heralded all over the land. But Cripple Creek can pour out her $1,500,000 of gold *per month*, and do it right along, and not be mentioned. The output of gold for the State in 1898 (some $25,000,000) justifies the rather boastful assertion of one of her daily papers: "Colorado has no rival in the production of gold within the limits of the United States." She has not found it profitable to push her silver industry, and yet her output of that precious metal is large. She mines, besides these, copper and lead, and coal, hard and soft (the area of the coal reserve has been likened to a cube whose sides are seven miles square), and iron fit for steel, in regard to which Mr. Andrew Carnegie is reported to have remarked, at a banquet recently that Pittsburgh was in a position to lay down iron in the markets of the world cheaper than any other locality in the United States with the exception of Colorado. She quarries the best of building stone of high crushing-strength, granite, sandstone of various colors, lava-stone, marble, and onyx. She is rich in flagging stone and paving stone. Here flow wells of oil and jets of natural gas. But it is in her agriculture and horticulture that she is most astonishing. It is quite within the memory of the writer when she was regarded as barren. "Do men gather grapes of thorns or figs of thistles?" one is wont to ask. And so one is incredulous that the land of the cactus, the sage-bush, or the red rock should produce anything but the cactus, or sage-brush, or the rock. No wonder then that the figures make the eyes stick out: 332 bushels of potatoes to the acre, one potato weighing 10½ pounds; oats, 7½ feet high, yielding 112½ bushels to the acre, and weighing 48 pounds per bushel; wheat giving 94 bushels to the acre are figures that make one see stars, even though these are the exceptional yields, and these figures are given on reliable authority. Wheat 27 bushels per acre, oats 40, barley 42, potatoes 132, alfalfa 4 tons; fruit $75 per acre, including young trees; full-bearing orchards $125 per acre; sugar-beets, yielding a factory value of $76.67 per acre. These averages, it is estimated, are fully maintained by the general yield in large areas of the several divisions. As amazing as all this seems, one feels as though it were a tale from the Arabian Nights, when he eats the delicious cantaloupe or muskmelon, or the crisp celery, or the Concord, big, round, juicy; or the peach, as big as a baseball, and as luscious as a Delaware, and is told that they come from Colorado. If one is in doubt, he has simply to ask his caterer.

But it is needless to pursue the subject further. In speaking of the Eastern country, Home, the Coloradoan formerly called it "God's country," in contradistinction to the barren plains and rugged mountain sides. Certainly it begins to look as though God had smiled upon this land, too, "thus inspiring man with confidence in his own resources, and facilitating the increase of his knowledge by encouraging that bold, inquisitive, and scientific spirit which is constantly advancing, and on which all future progress must depend."

As I have said before, Colorado offers ample opportunity for the most strenuous efforts of the most active. The plum is on the tree, but the tree has to be shaken. It is not every one who makes a winning, though the prize is there. Man has to struggle with the angel, but the fruits of victory are great and reward the effort. In Colorado a *man* can find opportunity, and would justly sing

"*Tecum vivere amem, tecum obeam libens.*"

THE OCCURRENCE OF CHEYNE-STOKES RESPIRATION DURING SLEEP A DIAGNOSTIC SYMPTOM IN THE EARLY STAGES OF INTERSTITIAL NEPHRITIS.

By CHARLES O'DONOVAN, M.D.,
of Baltimore, Md.

The occurrence of Cheyne-Stokes respiration in advanced stages of fatty heart and toward the end of the life of individuals suffering from one of the various forms of Bright's disease, as well as in other conditions of coma or allied states, has long been recognized. At such times it is merely one of many features marking the probability of an early fatal termination of the case, and attracting attention only as an interesting symptom of little diagnostic value. Experience has taught me to believe that this form of respiration may be one of the first symptoms observable in cases of chronic interstitial nephritis, giving warning of the sclerotic changes at a time when albumin is totally absent from the urine, or so infrequently present, or in so small quantity as to elude ready detection.

I have records of three cases each presenting this symptom at a time when no albumin could be detected in the urine; nor, in two of them, one a man and the other a woman, was there any other evidence of departure from perfect health. The third, a man, aged about sixty-five years, had well-marked arteriosclerosis with toughened radials. The first man was about fifty-four when Cheyne-

Stokes respiration was first noticed. He was a hard brain-worker, a great smoker, a total-abstainer from alcohol, a married man with a large family, of comfortable surroundings, and apparently in perfect health. He had never suffered from syphilis or any other venereal affection; his work kept him much in the open air; his appetite and digestion were excellent; he was rarely ailing, and then with trifling troubles. His urine was examined frequently, and contained neither albumin nor casts; his lungs were sound; his muscles were firm and strong; his heart was muscularly normal, but would occasionally intermit, dropping a beat at intervals of fifteen or twenty pulsations; otherwise it acted strongly and regularly. This irregularity was ascribed to over-use of tobacco, which he would not give up. He had been subject to severe attacks of headache ten to twenty years before I saw him, but these had been ascribed to neuralgia, and he was thought to have outgrown them. In the light of subsequent events it may be quite correct to accept them as the first symptoms of a prolonged course of nephritis. However that may be, at the time that I am now describing he showed no other symptom than the Cheyne-Stokes respiration, and that only at night. His wife, a woman of accurate observation, described it to me so truthfully that it could not be mistaken, as of nightly occurrence, at a time when he was in deep sleep. It was not always present, but appeared and disappeared without apparent cause, except that any overwork or worry would produce it, and in periods of relaxation it would be absent. This went on for fully seven years, until his death, the positive diagnosis of Bright's disease being made less than a year before the end. It may be interesting to note that, during the last six months of his life, he had several periods of a few days at a time when Cheyne-Stokes respiration was continuous during the day and night, unless relieved by opiates, and was particularly furious during the day.

The second case occurred in a woman who was under treatment for uterine trouble when her peculiar respiration was noticed, nocturnal only in her case also. She was about fifty-two years old and apparently perfectly healthy in every way, except for an intermittent discharge of pus from the cervix uteri. Her urine was examined several times without finding a trace of albumin; her heart and lungs were in every way normal, yet the Cheyne-Stokes respiration persisted night after night, especially after any fatigue or extra exertion. The case passed out of my hands after about six months of treatment and observation, but the patient died some three years later of Bright's disease, with uremic coma and convulsions.

In the third case, the man of seventy-two years, with atheromatous arteries and evident arteriosclerosis, the respiration was first noticed nearly four years before his death, and quite two years before albumin appeared in the urine. In his case, also, it was nocturnal entirely, and was noticed by his nurses, who had been instructed to be on the alert for such a manifestation. It occurred in greater frequency and with more force as his disease progressed, but never became evident in the daytime, as he died suddenly before any uremic symptoms had developed.

Small as is this group of cases they are of intense interest as they offer a suggestion that may assist in many instances in clearing up an obscure diagnosis. Many patients come into the hands of a physician with a train of symptoms that makes Bright's disease one of several possibilities. If albumin be not found by urinary analysis some other cause is assigned and most valuable time is lost when treatment would be most efficacious. When such subjects return months later with albumin present, the kidneys will have undergone such deterioration as to make it impossible to give any hope of a favorable result. It will be noticed that each of these patients presented the symptoms first at night exclusively, and even at that time only at irregular intervals. Careful observation over quite an extended period of time failed to show a single instance of its occurrence during the waking hours; when it appeared it was during sleep, otherwise calm and restful, and not influenced in any way, as far as could be discovered, by any particular posture or change of posture in the individual The subjects were well advanced in years, but showed, in two instances, no other symptoms that would lead one to suspect chronic nephritis; the arteriosclerosis of the third pointed clearly in that direction.

The value of this symptom as an aid to diagnosis depends very much on the accuracy of observation of the nurse or attendant of the suspected individual, but well-marked Cheyne-Stokes respiration is so very peculiar that a few lessons should be enough to teach any one to recognize it. Any trained nurse must have come in contact with it, and should know it at once, and any attendant, even without hospital training, would know it after a little instruction. It is unnecessary to urge the importance of the recognition of chronic nephritis at as early date as possible, before the kidneys shall have become irreparably damaged. If it is possible to arrest the advance of the disease, it must be in its earliest stages, and anything that will help us to a prompt diagnosis, or even to a reasonable suspicion, of such a fatal malady is worthy of careful consideration and extended study.

It would be of great interest to know whether or not Cheyne Stokes respiration is of frequent occurrence in the wards of large hospitals, where many cases of all kinds are grouped together, and where many opportunities are given for observation by night-nurses. From these patients could be eliminated such as would be likely to show this symptom in the usual course of the maladies from which they were suffering; the remainder should be carefully examined for evidences of nephritis, and the results of the examinations preserved for future reference, every effort being made to trace their subsequent histories. By collective investigation in this direction it is quite possible that a very material advance may be made in the early diagnosis of nephritis, at a time when such a diagnosis would be most valuable.

CLINICAL MEMORANDUM.

ESOPHAGOTOMY FOR THE EXTRACTION OF AN IMPACTED TOOTH-PLATE OF SIX YEARS AND FOUR MONTHS' STANDING.

By G. G. EITEL, M.D.,
of Minneapolis, Minn.

Miss A., aged twenty-seven, came to my office August 16, 1892, with the following history: Six years and four months previously she had been at a party, and while dancing, some passing incident caused her to laugh in such a manner as to throw her upper tooth plate out of her mouth on to the floor, breaking it into two pieces. Being more mindful of her personal appearance than of the danger of wearing a broken plate, she wiped the pieces with her handkerchief and replaced them in her mouth, wearing them during the rest of the evening. It being her custom not to remove her plate on retiring, she found to her astonishment on arising the next morning that instead of having two fragments of plate in her mouth she had but one, and she immediately realized that the lost fragment during sleep had passed into the esophagus. As it gave her no discomfort she paid but little attention to it, not even mentioning the circumstance to any one. About one year later when eating rather hurriedly and swallowing a piece of beef that had not been properly masticated, she discovered that it would not pass into the stomach, but was at once regurgitated, and from this time on she noticed the presence of an obstruction. She then consulted a physician, who, according to her story, advised her to leave it alone and pay no attention to it as long as she experienced so little discomfort. Subsequently the obstruction became so marked that she could not swallow any solid food whatever, and for a number of months she was sustained on liquids, mainly milk, many hours being required to swallow a teacupful of milk or beef-tea.

Fortunately the obstruction was low enough down so that quite a large quantity of fluid could be taken into the esophagus above the obstruction and allowed to pass as it might into the stomach. She became so accustomed to having fluid in this reservoir that she seldom went without it during the daytime.

The first thing to attract my attention when she consulted me was her general emaciation and cyanosis with dyspnea. An examination with an esophageal sound revealed an obstruction about two inches below the upper border of the sternum. From the click produced by the sound I was satisfied that the lost fragment of the plate was being struck, and that it was the cause of the obstruction. I made an attempt to grasp the plate with forceps designed for such purposes, but could not reach it. Her physical condition being such as to demand prompt relief, I at once sent her to the Northwestern Hospital, and with the assistance of Drs. Dunsmoor, C. T. Cook, and U. G. Williams performed an external esophagotomy.

The patient being anesthetized with chloroform, was placed on a table, her head somewhat elevated and her neck flexed in the direction of the right shoulder. The field of operation was brought as nearly as possible into an aseptic condition and an incision through the skin and platisma muscle was made on the left side, beginning at about the middle of the neck and extending along the anterior border of the sternocleidomastoid muscle down to the clavicle. This incision was gradually deepened, the anterior jugular vein clamped above and below and severed, and the sternocleidomastoid and omohyoid muscles, the common carotid artery, internal jugular vein, and the trunk of the pneumogastric nerve were drawn back with blunt retractors by my assistants. As the clavicle was approached due care was exercised not to injure the subclavian vein and arch of the aorta. A large-sized bulbed esophageal sound was introduced into the esophagus down to the obstruction, and an incision about one inch in length made into the lumen of the esophagus directly upon the bulb. With the point of the right index-finger I carefully dilated the upper part of the constriction and found a place where I could secure a hold on the plate with a small sequestrum forceps. It was with some difficulty dislodged and extracted.

I then made an attempt to pass an esophageal bougie into the stomach, but without success, as there was an almost complete stricture some distance below the point where the plate had been lodged. I finally succeeded in passing the point of a slender uterine dilator, by means of which a sufficient opening was made so that a large-sized stomach tube could be easily passed. The upper part of the incision was sutured, but on account of the vomiting during and after the operation it was impossible to prevent infection of the extensive wound, which finally healed entirely by the process of granulation. There was considerable discharge from the wound. Her temperature for a few days reached 101° F., and then gradually receded to normal.

The patient was fed with predigested food, per rectum, for more than a week, after which time milk and beef-tea were introduced into the stomach once a day through a tube. The rectal feeding was continued one week longer. She gained rapidly in flesh and strength. At

the end of four weeks the wound had closed, leaving quite a wide and ugly scar. This was completely removed by injecting a two-per-cent. solution of cocain along the skin margins, and after waiting about five minutes denuding the edges of the skin with a sharp scalpel and dissecting it for about an inch and a half on either side, the margins then being brought into apposition by means of fine silk stitches placed close together. A large-sized esophageal bougie was passed once a week for about two months.

There seemed to be but little difficulty in respiration after the plate had been removed from the esophagus, and no hindrance to deglutition at any time after the fistula had closed. The patient began to enjoy excellent health almost immediately after the operation, which is still her good fortune, almost six years having passed since that time.

MEDICAL PROGRESS.

A New Process of Skin-Grafting.—Wiggins (*St. Louis Clinique*, July, 1899) has attained complete success in skin-grafting by scraping epidermic cells from the sole of the foot. The foot is prepared by a thorough scrubbing, to remove as far as possible the outer layer of epidermis which must of necessity be alive with micro-organisms. This is followed by bathing in strong bichlorid solution; the foot is then covered with moist boracic-acid dressings covered with rubber tissue, which serves, by reason of heat and moisture, to loosen the deeper and more vitalized layer of cells. After twelve hours the dressing is removed and the surface thoroughly scaped with a dull knife. The cell mass thus obtained is placed in a mortar which in turn is placed in a water bath at a temperature of 110° to 115° F. and stirred until thoroughly desiccated. This procedure triturates and further separates particles, and divests them of all moisture, so that they will better adhere to the moist surface of the ulcer. It is readily understood that in a certain space where by the ordinary method there is but one graft, by this method there will be perhaps 1000, and on account of the minuteness of the cell or cells, the chance of their living is increased. The dangers which a graft is likely to encounter are: (1) excessive secretion which will wash it from its anchorage, and (2) the formation of exudate between the graft and the granulating surface which will prevent union and result in the death of the graft. These dangers may be avoided in two ways. One may take a piece of ordinary rubber tissue, perforate it, leaving the holes at intervals of one-eighth of an inch, and cover with it the entire surface. Through these holes islands of granulation tissue will protrude about one-quarter line above the surface, each independent of its fellow. The intermediate pressure serves to render the projecting points more vascular, and thus facilitates union with the grafts.

Another method consists in marking off a space of granulating surface around the entire circumference one-half to one-quarter of an inch wide and sowing this field with desiccated epithelial cells, over which strips of rubber tissue are laid, extending about one-half line beyond the margin of implantation. The center of the ulceration is then filled with strips of gauze and dressings are applied in the usual manner. If the surface to be covered is less than two inches wide, these special methods of procedure are not necessary and the epidermic cells can be spread completely over the granulating area. The results which Wiggins has obtained have been most satisfactory. An ulcer one inch by one and one-half inches may be entirely covered by a thin film of organized tissue within twenty-four hours, and within ten days it may be impossible to discriminate between the old and the new structures.

A New Method of Treating Echinococcus.—Garee (*Centralbl. für Chir.*, July 15, 1899) mentions three cases of echinococcus of the liver in which he followed the method of Bobrow, scraping out aseptically the contents of the cysts, closing them with a continuous suture, and returning them to the abdominal cavity. The first operation was followed by the formation of a fistula but inside of a month the patient recovered so far as to be able to walk about and to return home. In the second case an enormous cyst of the left lobe of the liver was partially resected and partially sutured and dropped back. Recovery in this instance was prompt, as it was in the third case in which a cyst the size of a man's fist was adherent to the colon, omentum, and liver. A part of the cyst-wall was resected and the remainder sutured. These cases show the possibility of obtaining primary union of echinococcus cavities after the contents have been removed. The chief objection to this method, according to the writer, is the danger of leaving behind some of the infectious material if the cyst is exposed with difficulty or if daughter cysts are present. In the fourth case Garre punctured through the rectum an adherent cyst in the pelvis and injected into it a solution of corrosive sublimate. One year later no trace of the tumor was to be found. This method of treatment is only recommended in case the adhesions completely shut off the peritoneal cavity.

Malaria of a Pernicious Form Cured by Hydrotherapy after the Failure of Treatment by Quinin.—Lemoine and Veuillot (*Le Nord Méd.*, July 15, 1899) relate the history of a patient aged thirty-one years, who suffered from malaria of an aggravated type. Chills and fever occurred irregularly and were only temporarily and partially relieved by the administration of from 30 to 60 grains of the sulphate of quinin per day. Hypodermic injections of quinin and of cinchonidia were equally unsuccessful. Things had gone on in this manner for three months and the patient had lost all appetite and vomited almost all food. The medicine was discontinued and the patient was subjected daily to treatment by a stream of cold water directed upon the chest, arms, back, and legs. At first the douche was given for only ten seconds, but the time was gradually increased until it lasted a minute. The temperature of the water was 45° F. The chills and fever disappeared almost immediately, the general condition began at once to improve, and in a short time the patient was entirely well.

Paravaginal Hematoma—Voiturez (*Centralbl. fur Chir.*, July 15, 1899) describes the paravaginal space as

lying between the outside layer of the tunica vaginalis of the testicle and the inner layer of the tunica fibrosa. This paravaginal space may be the seat of a hematoma as has long been known. A predisposing cause is the presence of an old varicocele or hydrocele. The immediate cause is usually a trauma, such as a blow or a fall, although a hematoma may be caused by the needle used to tap a hydrocele. Paravaginal hematomata have usually an irregular, oblong shape. They vary in size and may be as large as two fists. In vaginal hematoma the testicle and clotted blood form one mass, but in paravaginal hematoma they can usually be distinguished one from the other by palpation. Spontaneous cure is not likely. Usually the blood remains encapsulated and the surrounding fascial layers thicken; or infection may take place with suppuration. If the patient is seen in the early stage, an incision should be made to evacuate the blood-clots and the wound should be treated by pressure and a drain until it heals. If the hematoma has existed for a long time and its walls are thick, they should be resected as far as possible. If a hydrocele is also present this should be treated by the open method.

A New Method of Expelling the Placenta.—Budberg (*Centralbl. für Gyn.*, July 29, 1899) recommends the following modification of Credé's method of expelling of the placenta. The patient's attention should be distracted in order to secure relaxation of the abdominal muscles. After slight rubbing movements, the hand of the obstetrician sinks gradually deeper until it grasps the fundus as much on the posterior wall as possible, the thumb being directed forward. With the other hand the lower portion of the uterus is seized in such a manner that the ulnar edge of the palm lies against the symphysis. Expression should begin with a pain and increase during its continuance. The two hands should be pressed together, harder and harder, as the pain increases and as it passes over the pressure should be gradually lessened and not suddenly removed, even though the placenta is expelled in the meantime. With the upper hand rubbing movements are to be made as they were made at first. It is claimed for this method of expression that it does not move the uterus out of its normal position, but rather fixes it in that position, so that there is no danger of tearing the ligaments or the peritoneum of Douglas' pouch; nor is inversion of the uterus possible. This method of expression also empties the urinary bladder.

A Self-Retaining Drain for Empyema.—Felkl (*Prager Med. Woch.*, July 6, 1899) describes the use of a special form of drain in empyema. He took a short glass tube, flattened it slightly, and at a point where the ribs would press upon it, indented its sides, thereby making a shallow groove. A rubber tube of the same diameter as the glass tube was drawn tightly over it. The groove was plainly shown through the rubber. The diameter of the glass tube was 8 |mm. (⅓ inch) and the length of the rubber tube 35 cm. (14 inches). The portion which projected inside the chest was furnished with numerous fenestra. The patient was not inconvenienced by the slight pressure of the drain between the ribs and owing to the accurate closure, drainage was perfect and in less than two months the wound had entirely healed. No irrigation was employed.

Slipping of the Intraperitoneal Ligature.—Sutton (*Buffalo Med. Jour.*, August, 1899) says that the slipping of a ligature placed upon an exposed vessel is due either to careless application or to giving way of the knot. The latter possibility may be ignored when silk is employed. A catgut knot in the peritoneal cavity may slip. For this reason when several blood-vessels are ligated together, he always uses silk. No matter how carefully tied, a ligature may slip off a mass of tissue, or, more properly speaking, part of the constricted mass, especially that which contains the artery, may retract from the ligature and so give rise to hemorrhage. In order to avoid this unfortunate accident, it is necessary to leave a sufficient stump for the ligature and before the ligature is applied a groove of crushed tissue should be made in the stump by means of a pair of heavy clamps. When this is done there is no danger of the ligature slipping off. Tying tissue *en masse* is not surgical and endeavors should be made in all cases to tie the arteries themselves. Doyen's crusher may serve a useful purpose in all cases where it is not possible to apply a ligature with safety; but one ought not to rely on it to the exclusion of sound surgical methods.

The Micro-organism of Scarlet Fever. — Class (*The Sanitarian*, August, 1899) has found, as he believes, the micro-organism of scarlet fever. It is a diplococcus resembling, as ordinarily seen on freshly made slides, a large gonococcus. The size varies somewhat but it is always considerably larger than the ordinary pus-microbe. Usually these cocci occur in bunches of from ten to fifty. Streptococcic forms are occasionally met with. The organism has no capsule. It does not show any spores, has no flagellæ, and under examination by the hanging-drop it does not show any independent motion. It is decolorized by Gram's method although not to the same extent as the gonococcus. The germ described has been cultivated from the scales in about thirty typical cases of scarlatina. It has also been found in the angina of scarlatina, and in cases of angina occurring in persons exposed to scarlet fever in whom no eruption shows. The writer also found it in the throats of children in a family, one member of which had scarlatina although the children were well at the time the culture was made. Subsequently these children developed scarlatina and the germ was cultivated from their scales. Class hesitates to say that this is the specific germ of scarlet fever. He is making further experiments along the same lines. A culture of the micro-organism injected into the ear veins of swine has produced a disease closely resembling scarlatina in the human being. From the blood and scales of the inoculated animal the same organism has been isolated. The germ will not grow in agar-agar nor in bouillon. Class used a glycerin agar-agar to which was added a thin paste containing five-per-cent. of dried and sifted garden earth mixed with bouillon and boiled.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 16, 1899.

SIMPLE ROTATION OF THE BODY FOR VOLVULUS.

Volvulus is usually so serious a condition, frequently requiring operative interference, that a heroic method of treating patients who have symptoms of the condition seems well worth noting. Dr. G. H. Hunter in the London *Lancet* for August 19, 1899, reports four cases in which the simple rotation of the body of the patient around its long axis while in the horizontal position brought almost immediate relief of the symptoms, especially of the pain, and eventual recovery without further treatment.

Of course there always remains a certain amount of doubt as to the real lesion that has existed in the intestines of patients who recover without laparotomy. Dr. Hunter's cases as described, however, presented symptoms that would ordinarily be considered amply sufficient to justify his diagnosis of volvulus, and if it were not volvulus, then a method of treatment that will relieve pain in certain obscure abdominal conditions as promptly and as completely as this deserves to be given a thorough trial.

The patients are asked first to gently make a half turn to the right or to the left, keeping themselves as far as possible in the horizontal position. If the pain is greatly increased by this half turn, then the patients are asked to turn the other way until three or four complete revolutions of the body are made. The relief of pain is almost immediate and is usually appreciated after the first turn. Dr. Hunter suggests that the method may be of use as an aid to diagnosis in suspected cases of volvulus. If a half turn of the patient to the right or left causes increase of pain it may be concluded that some twisting of the intestines with consequent congestion and cramp is the explanation of the abdominal symptoms complained of, the rotation making the condition worse.

LEGAL REGULATION OF BARBERS.

It is a well-known fact that certain very troublesome, though fortunately not very serious skin affections are easily and very commonly acquired in barber-shops. The number of chancres of the face and lips reported every year as acquired during the shaving process, is, especially in European countries where syphilis is more general, continually on the increase. Last year we called attention to the fact that in Austria and a little later in Germany, a law had been passed requiring barbers to know the general features of asepsis and making compulsory its enforcement in the regular barber-shops. Other countries followed the good example thus set, and now we note with pleasure that the Province of Quebec has passed a law, which goes into effect almost immediately, which promises to effectually limit the possibilities of the spread of infection through the medium of the barber-shop. A noteworthy feature is that all barbers before they take up the practice of their trade must present the certificate of a physician in good standing that they are not suffering from any contagious disease. Besides this they must pass an examination showing that they possess a knowledge of the proper method of disinfecting their implements and sterilizing their towels and hands.

We can readily understand that such a law, unless hedged in by most careful precautions, may be abused by labor unions for purposes not conducive to public utility. The principle involved in the law, however, is so thoroughly commendable that even this risk may be calmly faced. It is besides in perfect

accord with the modern advances in preventive medicine. Patrons will submit to a barber's manipulations with a feeling of greater security when they realize that intelligent efforts are made to keep implements and towels and hands reasonably sterile. Many who now hesitate to use public barber-shops will be given confidence in them, so that the extra expense involved in the observance of the law will be more than repaid in the ordinary course of business.

TRUSTS AND MEDICAL CHARITY.

THE Lord Mayor of London called attention in a recent letter to the English press on behalf of the Metropolitan Hospital Fund to a matter which has already been publicly mentioned in England more than once. It is the loss to charity and especially to hospital funds generally of many generous contributions, because many of the old and wealthy firms have been turned into limited liability concerns which have no power to contribute from their corporate income to purposes of charity. The London *Lancet* says with regard to the matter: "It is of course no part of the duty of the directors of such companies to propose that any part of the dividends should be set aside for charitable purposes, but it is possible and even probable that if the Lord Mayor should address a letter to such companies asking for subscriptions to the Hospital Fund the matter would be discussed at the meetings of the directors and a donation granted."

We have not as yet heard any complaints in this regard in this country. It seems probable, however, that in the present fad for the organization of manufacturing concerns into trusts in order to reduce the fixed charges, that one of the fixed charges that will suffer from the new economy will be the contributions to hospitals. Proverbially corporations have no souls and the larger they are the more completely material do they seem to become. Let us hope that in the reorganization ensuing in so many large interests the claims of the hospitals which do so much for their workmen will not be forgotten. More than this let us hope that the managers of public institutions will at the first sign of a falling off in contributions as a consequence of trusts and consolidations make such representations as our London contemporary suggested to the proper authorities and so prevent their efficiency from being even temporarily impaired by an oversight.

NEW AIDS IN THE EARLY DIAGNOSIS OF TUBERCULOSIS OF THE LUNGS.

THE interest aroused in everything connected with tuberculous disease by medical and popular movements for the treatment of the affection in sanatoria and by the recent Congress on Tuberculosis at Berlin has only made more emphatically clear certain old and well-known points with regard to the disease. It is now universally conceded that there is no pharmaceutical specific for tuberculosis and that even climate and altitude, for so long supposed to have a certain specific curative effect, are only especially favorable elements in the general hygienic conditions that constitute the best treatment up to date. It has, however, become clearer than ever that treatment to be successful (and it can be completely successful in opportune circumstances) must be begun early. Early diagnosis is the all-important factor for the cure of pulmonary tuberculosis. It is much more essential for the patient than any studied dietary or régime in ideal conditions of light and air that his physician detect the disease at its very outset. Every aid to diagnosis that promises even a modicum of assistance in the delicate question of the detection of an incipient tuberculous process in the lungs must be familiar to the conscientious physician who takes on himself the responsibility for these cases. It is no longer enough to be able to apply with advantage the ordinary methods of physical diagnosis or even to detect bacilli in the sputum. There are certain other aids that it would seem every physician who sees many of these cases should be familiar with.

Two of them have been brought into such prominence recently that it seems advisable to call special attention to them once more. At the recent meeting of the American Climatological Association in New York City an animated discussion brought out the fact that laryngologists believe that there is often present in incipient tuberculosis a condition of the larynx which, while not pathognomonic of the disease, always should arouse active suspicion and lead to careful examination of the lungs. This is not a tuberculous laryngitis, but is an anemic condition of the mucous membrane of the larynx in which the membrane itself seems thinned and almost atrophic, and blood-vessels stand out prominently in it. Dr. Lenzman, in the June number of the *Therapeutische Monatshefte*,

calls attention to this characteristic pale appearance of the laryngeal mucous membrane, and says that it may also sometimes be noted on the soft palate and even on the hard palate. The anemia of the larynx sometimes gives rise to a dry, irritative cough. It is the cough that patients come to be treated for, and it is possible that the laryngeal appearance might be considered sufficient to account for it, especially as it is not a productive cough. On the contrary, the laryngeal condition seems to be a reflex nervous interference with the blood-supply of the larynx consequent upon the pulmonary affection and it is the pulmonary condition that demands attention.

At the same meeting of the American Climatological Association Dr. Francis H. Williams of Boston called attention to the fact that the Röntgen rays may be of great service in revealing incipient consolidation at the apices of the lungs before it is demonstrable by the ordinary physical signs. He pointed out also that the excursion of the diaphragm on the affected side is usually less than that on the sound side very early in the disease. Dr. Cabot of Boston, in the issue of the MEDICAL NEWS for April 15, 1899, called attention to the utility of Litten's phenomenon in revealing this same impaired motion of the diaphragm on the affected side. The excursion of the diaphragm may be seen in many cases by simple inspection to be distinctly lessened without the expensive apparatus necessary for the X-rays.

These laryngeal and diaphragmatic phenomena have not been called especially to the attention of the general profession before, and it would seem as though they may prove of distinct service in confirming other suspicious signs in the early stages of pulmonary tuberculosis when diagnosis is often so very difficult and yet so very important.

ECHOES AND NEWS.

Dr. James Campbell of Hartford has resigned the professorship of obstetrics in the Yale Medical School.

The Volta and Galvani Historical Relics.—It is now definitely settled that the fire at the Electrical Exhibition at Coma in Italy entirely destroyed most of the relics of the work of these, the original electricians. Only Volta's pile and some letters and manuscripts remain of the very interesting collection that was sent to the exhibition.

Tri-State Medical Society of Alabama, Georgia, and Tennessee.—The eleventh annual meeting of the Tri-State Medical Society will be held at Chattanooga, October 24, 25, and 26, 1899. Those desiring to read papers should send titles to the Secretary, Frank Tresler Smith, M.D., Chattanooga. The indications are that the meeting will be large and successful.

Death of Karl du Prel. — The death is announced of Karl du Prel, the German spiritualist, who up to 1872 was a captain in the army, and who retired in that year to devote himself to literature. He wrote many books in behalf of mysticism, and had many savage controversies with medical men, who had no difficulty in showing that his delusions were due chiefly to his ignorance of mental pathology.

Many Soldiers Ill. — The New York *Evening Post* of September 9th states that in General MacArthur's Division in the Philippines 36 per cent. of the officers, and 25½ per cent. of the enlisted men are ill. This includes the sick in quarters and those sent home. Eleven per cent. of the men sick in quarters are suffering from dysentery and malarial fevers. The *Post* vouches for the accuracy of this statement which it declares the censor has refused to telegraph.

Recovery from the Bite of a Gila Monster.—A snake charmer at Coney Island not long ago was bitten on the hand by a Gila monster. The bite of the creature is sometimes fatal and always serious. The immediate application of a tight bandage around the wrist prevented the absorption of the poison into the general circulation, while suction by the patient himself, and free bleeding, aided in getting rid of it. The patient recovered without any very serious symptoms and without sequelæ.

Christian Science Held to Be Legal. — Attorney-General Akin of Illinois rendered an opinion on September 9th to the effect that the Medical Practice act of 1899 does not prohibit the treatment of disease by mental or spiritual methods by Christian Scientists or others, when no medicine is used, and that when a person dies under such treatment it is not an offense under the criminal code of Illinois. Attorney-General Akin is not the first legal luminary who has not been able to separate medicine and pseudo-theology.

Italy's Plague Serum.—For three years the Institute of Hygiene at Messina, Sicily, has paid, under the direction of Professor Terin, much attention to the study of the plague bacillus and to the production of a special serum. Professor Terin and his colleagues have great faith in the qualities of the serum, and two of his assistants, Drs. Bandi and Stagnitti, have gone to Oporto for the purpose of using it in that city. The authorities of the Messina institute believe that their serum and the vaccine produced in their laboratories will give results superior to the same preparations furnished in France and Germany.

Hospital Corps Men Needed. — The work of providing hospital corps men and trained nurses for the enlarged

Philippine army continues to give Surgeon-General Sternberg and his colleagues some concern. According to the calculations of the medical officers at the War Department, it will be necessary to have an aggregate of 2000 hospital corps men ready for service when the fall campaign opens. At this time nearly 1000 of these remain to be enlisted. Special efforts are being made to secure good men for this service, but the recruiting is progressing very slowly, owing to the desire to enlist in the volunteer infantry regiments.

Memorial to Plague Martyr.—We noted some months ago the death of Surgeon-Major Evans of the British India Military Medical Service from plague contracted while performing autopsies on the bodies of victims of the bubonic plague. It is now announced that the fund raised to commemorate his untimely death will suffice not only to erect a suitable tablet, which was the original intention of the promoters of the fund, but will also be sufficient to establish a small prize in pathology at the University of Calcutta. A fitting tribute this to a brave man, and one calculated to do good by holding up his example for emulation while perpetuating his memory.

Hours of Sunshine per Year.—According to the *Scientific American* these are the number of hours of sunshine annually in various European countries as given by the French Meteorological Bureau at Paris: Spain, 3000; Italy, 2700; France, 2600; Germany, 1700, and England but 1400. The average fall of rain in the latter country is greater than that in any other European country. In the northern part and on the high plateaus of Scotland about 351 inches of rain fall each year, and London is said to average 178 rainy days in the year, and fully ten times the quantity of rain that falls on Paris.

St. Louis' New City Hospital.—The new hospital in St. Louis for which ground has just been broken will when completed cost several million dollars, and will be perhaps the most complete and perfect institution of the kind in the world. The pavilion plan has been adopted and the buildings first to be put up are the central administration building and a few of the surrounding pavilions. It will be some years before all the buildings called for by the plans will be constructed. A clause in the city charter permits one per cent. of all the city revenue to be used for this purpose. This represents at present an annual allowance of $225,000. The plans were drawn after a study of the best hospitals of Europe and America.

A "Power" Brake for Trolley-Cars. — The New York State Railway Commission is carrying out a series of tests on Lenox avenue, this city, to determine the efficiency of certain safety brakes. The number of serious accidents, many of them fatal, that take place on street-car lines throughout the country makes the employment of some safety device for the rapid bringing of cars to a stop, an absolute necessity. Hundreds of lives would be saved every year if there was some means of stopping a street-car within its own length. Modern electric cars are so heavy, and are run so rapidly, and carry so many passengers, that it is preposterous to expect an ordinary hand-brake to do effective service on crowded city streets. The present move of the State Railroad Commissioners deserves every encouragement, and we hope that it will result in the enforcement of some regulation requiring the equipment of all street cars with an effective form of power brake.

The Yellow-Fever Situation.—The present conditions of the outbreak of yellow fever are more serious than when we reviewed the subject last week. Up to the beginning of the week 200 cases of yellow fever had been reported at Key West and about ten new cases a day were occurring. A case of yellow fever is reported from Port Tampa, Fla., and the report is confirmed by the autopsy. One case of yellow fever, but that of a malignant type, occurred at Jackson, in Mississippi. Other towns in Mississippi are beginning to quarantine strictly against infected places. At New Orleans no new cases have been reported, and the fever seems well in hand. Four cases of yellow fever were at quarantine in New York City at the beginning of the week. They had been brought North on the steamer "Lampasas" from Key West. One of the cases proved fatal on Monday night, but it is expected as we go to press that the others will recover. The New York City quarantine authorities are carefully watching all passengers from Key West, and are confident that they will keep yellow-fever patients from landing at this port.

Barbarism and Civilization. — Two French officers in Africa have been guilty of conduct which well deserves the attention of the alienist and the student of human evolution. Captains Voulet and Chanoine have been charged with barbarous cruelties to the natives in the French Soudan. For instance, a native was beheaded because he declared he did not knew a road about which he was being questioned. Voulet, it is said, captured eighty natives, among whom he killed twenty women and children. Chanoine burned a village and captured twenty of its inhabitants, ten of whom he killed, placing their heads on pickets. It may be said that such conduct is to be expected of a people which has just for a second time convicted of treason a perfectly innocent man. But for an explanation we must go deeper than this. It is known that English officers, who were considered gentlemen of the finest instincts while at home, committed the most hideous barbarities while in Africa. Dr. Peters, the German explorer, has been while in Africa guilty of unspeakable acts. It appears that it takes many centuries for man to advance from savagery to civilization, while the relapse is practically instantaneous.

Protective Inoculation for Plague.—Of special interest, owing to the present plague situation, is Captain Leumann's report on preventive inoculations against plague at Hubli in India during the past year. Captain Leumann, who was detailed for the purpose of investigating the effects of Haffkine's serum, was very well satisfied with the

results. One of the most interesting things in his report is the fact that those twice inoculated with the serum were much more surely protected from plague than those but once inoculated. The statistics he gives are very striking. The disease was not of a mild type, for in one week the mortality stood among those who held aloof from inoculation as high as 657 per 1000. The town could not be evacuated, and therefore, concurrently with disinfection, unroofing of houses, and segregation, the inoculations were vigorously applied, so much so that in a short time more than 24,000 were inoculated twice, and 10,000 once. The results are remarkable, indicating a protection of 85 per cent. on the whole epidemic, with a figure of from 90 to nearly 100 per cent. for the greater part of the time. The twice inoculated show a record just over 10 per cent. better than the once inoculated.

A Final Word about the Kissing-Bug.—After the excitement and exaggeration indulged in with regard to the so-called "kissing-bug," it seems well to be prepared for any future visitations of the troublesome insect by definite scientific knowledge. This is all the more interesting as it serves as an explanation of certain severe insect bites usually attributed to spiders. At the recent meeting of the American Association for the Advancement of Science Dr. L. O. Howard, United States Entomologist, treated the subject very interestingly and practically. His paper, a brief abstract from which we clip from the *Scientific American* for September 9, 1899, was entitled "On Some Heteropterous Insects Formerly Responsible for Spider-bite Stories." He said that while, after several years of investigation, he had failed to verify by proof even a single case of serious or fatal spider-bite, he found that several bugs belonging to the *Reduviidæ* do inflict painful wounds. He described particularly the *Reduvius personatus*, an imported European species, the *Melanolestes picipes*, and *M. abdominalis*, allied native species, and two varieties of *Rahasus*, and several kinds of *Conorhinus*, all of which occur in this country, and whose bites have often been attributed to spiders. He regarded the "kissing-bug" craze as phenomenal, and largely due to stories told by the newspapers, based upon a comparatively small number of actual cases. It reminded him of the tarantula frenzy that was once epidemic in Europe, with remarkable psychological manifestations, which had thus been reproduced this year in a mild form. Curious instances were told of nervous and even hysterical symptoms that had been produced by simple mosquito bites. The paper was accompanied by an exhibition of specimens and drawings.

The Plague in Portugal.—Up to the end of the second week of September about sixty cases of plague with about one-third that number of deaths had occurred in Portugal. A new case is reported nearly every day. The Portuguese authorities seem to be doing their best to prevent the further spread of the disease. Eight battalions of infantry are patrolling the country in the neighborhood of Oporto, and are supposed to absolutely prevent ingress to or egress from the city except with proper precautions. Dr. Vincente, who was sent by the Spanish Government from Madrid to investigate the plague at Oporto, reports that the prevalent type of the disease is the pneumonic form, and that he considered the epidemic a serious one. This form of the disease is said to be especially contagious. The *British Medical Journal* thus sums up the situation in Portugal: "The disease seems to spread. In one of the Oporto jails a prisoner died of plague. Suspected cases have occurred at Lobrigos, Regoa, San Samedi, and at Tambuija, and Atalaya, north of Santarem, on the railway between Oporto and Lisbon. The populace in Oporto are hiding their sick, not only the plague stricken, but persons suffering from ordinary illness. This is proved by the attendance at the public hospital, where the daily number of out-patients has fallen off. At the Misericordia Hospital the out-patients are only 48 daily, in place of 220. The poor believe that once sent to the hospital on suspicion of having plague that they are straightway poisoned. The only official means of exit from Oporto is now by sea, but it would seem, however, that plague has infected the country beyond the cordon, so that, as so often happens, the soldiers forming the cordon may, as the infected zone is included, become the means of spreading the disease.

The Plague Situation.—Generally the plague is milder everywhere than earlier in the summer. It is to be noted, however, that it has often been remarked before, that toward the end of the summer there is very little of the disease, and then an outbreak occurs in infected spots when cold weather sets in. At Alexandria not more than two or three cases a week are being reported. In Mauritius, during the last week in August, there was a recrudescence of the disease and some forty cases and over thirty deaths occurred. At Hong Kong, according to official statistics for the week ending August 27th, there were fifteen new cases and fifteen deaths. It is officially confirmed that plague exist at Nieuchwang in China. It has been found very hard to understand how the plague succeeded in reaching Nieuchwang which is 1500 miles from the nearest infected port in China, Amoy, and it is feared that other places along the coast may prove to have the disease. The plague situation in Russia is the cause of no little uneasiness in Russia itself, and also to European countries having commercial relations with her. The suspicious disease which recently broke out at the village of Kolobooka, in the Province of Astrakhan, seems to be plague of the pneumonic form. A large number of deaths are recorded, and the matter is considered so important that the Duke of Oldenburg, the President of the Committee for Combating the Propagation of Plague, has gone to Kolobooka, accompanied by a number of medical men. The Roumanian authorities have, in consequence of the news from Russia, closed the Russo-Roumanian frontier, and passengers are allowed to pass only at four of the frontier towns. The Russians have placed military observation posts all along the infected border, and persons from Astrakhan will not be permitted to cross the frontier at all. All goods are being disinfected, and a ten days' quarantine is, in addition, insisted upon.

MEDICAL MATTERS IN NEW YORK.

CREMATION BY LIQUID AIR—TEMPERATURE DURING THE SUMMER—TO EDUCATE THE BLIND AND THE DEAF—LEPER DIES ON BLACKWELL'S ISLAND—VACCINATION OF SCHOOL CHILDREN —COMPTROLLER COLER AND THE CHARITIES.

PLANS for a large liquid air crematory to be established at the Nyack Rural Cemetery, New York, have been prepared. The work will commence at once under the management of Dr. Emmons, President of the American Liquid Air Company, of New York.

The temperature of New York, on the average, has been quite low during the past summer, and the weather has generally been delightful. Other places have fared much worse. London has passed through the hottest summer since its meteorological bureau was established twenty-seven years ago. Chicago has of late been suffering intensely, the thermometer having at times reached 102° F. in the shade.

Richard Young, Esq., a member of the Brooklyn School Board, has proposed to establish classes in the public schools for the education of blind and deaf children. He considers that as there are no schools in Brooklyn for the education of blind children, a part of the public funds should be devoted to this purpose. Moreover, children who, while they are not blind, have defective eye-sight, and are for that reason kept out of school would also be benefited by the proposed classes.

Ling Jug, a leprous Chinaman, died on September 7th in a hut on Blackwell's Island, in which he had lived for two years past with another leper. In 1897 Ling Jug and three other Chinamen were isolated on North Brother's Island. Ling and the companion who was with him at his death got away in a rowboat but were captured and sent to Bellevue Hospital, whence they were sent to Blackwell's Island. This case recalls that of Joe Evans, the leper, who served the twenty-four internes in the "Doctors' Hall" at Charity Hospital. He sold them cigarettes, stamps, etc., prepared their bichlorid baths, and was in constant attendance upon them. His case was one of leprosy well developed. His propinquity seems to have hurt no one.

Health Board President Murphy's instructions that the school law concerning vaccination must be strictly enforced, is bearing fruit. Two new vaccination schools have been opened, at 68 Elm street and in the Board of Health building, at Sixth avenue and Fifty-fifth street. The physicians at both these places have been busy attending to the many comers. The law states that "every child of school age who has not been vaccinated within six years, must submit to the operation under penalty of exclusion from the city schools." All precautions are taken by the Health Board physicians. In every case a new needle is used to scratch the arm, and by means of a fresh, unused splinter of wood the virus is spread over the wound. While the Health Board facilities are intended primarily for children about to enter school any one who desires may take advantage of them. In 1898 there were vaccinated 521,747 persons, and no doubt the number will be increased this year.

At the meeting of the Board of Estimate on September 7th, Comptroller Coler presented a report favoring several important changes in the disbursement of city funds among private charitable institutions. Copies of letters of suggestion and advice from the State Board of Charities (which have already been noticed in this column), from the New York Medical League, the Charity Organization Society, the State Charities' Aid Association, and extracts from various other reports are appended to this report, together with tabulated statements from the institutions themselves, the whole making a pamphlet of 100 pages. The report refers to the passage in 1894 of a constitutional amendment providing that the Legislature might authorize, but not compel, public support for private institutions. This amendment was intended to stop the custom, which had obtained among private charitable institutions, of going directly to the Legislature instead of to the Board of Estimate for public help. It was not, however, retroactive. The report further points out that the Stranahan amendment to the charter is destined to revolutionize the relations existing between the city treasury and private eleemosynary institutions. It authorizes the Board of Estimate to appropriate money for the aid of private charitable organizations and to increase or diminish the amounts of such aid regardless of the recognition which any institution may, or may not, have obtained from the Legislature and regardless also of the amounts fixed in prior budgets. Since the passage of this amendment the Comptroller has been investigating the subject of municipal aid for private charities. In 1898, it is shown, the city expended $2,334,456.49 for prisoners and public paupers, and $3,131,580.51 for paupers in private institutions. As compared with the latter figures Chicago expends $2796; Philadelphia $151,020; St. Louis, $22,579.30; Boston, nothing; Baltimore, $227,350; Cincinnati, nothing; Cleveland, nothing; New Orleans, $30,110; Washington, nothing; Detroit, $194,500; Milwaukee, nothing; Newark, $7,500; Jersey City, nothing, and Minneapolis, $2000. About 21 per cent. of the cost of the maintenance of dependent children is borne by private benevolence in New York, while 97 per cent. is so borne in Philadelphia.

The Comptroller suggests that all appropriations of public funds for charitable purposes should be made only from the budget, instead of, as now, from the Excise Tax Fund and the Theatrical and Concert License Fund; and that the appropriations be made upon a uniform pro rata basis, all accounts of the institutions receiving aid to be kept so as to show the receipts and disbursements of public money separately, the disbursements being solely for annually recurring expenses of "care, support, and maintenance." There is at present no such basis for appropriations. The report states: "Eighteen institutions caring for dependent children are paid per capita $2 per week; sixteen are paid 25 cents per day; one is paid $104 per annum, and three $110 per annum. Four medical charities receive for infants 38 cents per day per capita; two receive $10 per month. Three lying-in hospitals receive for mothers, $18 per month; two receive $5 a week and one receives $12 a month. One receives $15

for each obstetrical case, and five receive $25. Three hospitals receive $1 per day for each patient, while three receive that amount only for surgical cases, obtaining only 70 cents per day for medical cases. Three reformatories receive $110 per annum; one $150 per annum, and one $2 per week. Seventy institutions receive appropriations aggregating $350,000 in bulk, *i.e.*, upon no basis of payment for actual service performed. It may be doubted whether the spirit of the constitutional provision prohibiting the donating of public money in aid of private individuals and corporations (with an exception in favor of the support of the poor) is complied with in the case of the appropriations made in bulk to institutions, regardless of the quality or extent of the services rendered in consideration thereof. Furthermore, if the charitable work performed by an institution is of such a character as to make it impossible to measure the value of the services rendered to the city, it may well be doubted whether that work can be of such a character as to warrant the donating of public funds.

"An examination of the returns made by institutions receiving appropriations in bulk from the city treasury, shows that many of them are using the public funds for purposes not authorized by the Constitution. The Constitution authorizes payments to be made for 'care, support, and maintenance.' The reports of a large number of institutions show the money annually obtained from the city carried forward wholly or in part as surplus. Different uses are made of this surplus, none of them, however, authorized by law, or warranted by a proper regard of the interests of the taxpayers. In some cases this surplus is used to pay off mortgage indebtedness, in others for permanent additions to buildings or for increase of investments and endowment. In one case the manager of an institution frankly explained a remarkable falling off in disbursements (so great that its charitable activities were almost suspended) by stating that it was proposed by exercising great economy for a number of years to let the city's annual appropriations accumulate into a respectable building fund. The flagrant nature of this abuse is so apparent that argument is unnecessary."

The resolution appended to the report provides that all institutions receiving public money shall at all reasonable times be open to the visitation and inspection by representatives of the Public Charities and Finance Departments, and that payments of appropriations may be withheld by the Comptroller if it appears to him to be to the public interests thus to do. Appropriations for dependent children receive special attention in the report. It is stated that 69 per cent. of the money appropriated for private charity in 1898 was for children. There were 50,638 children, or one for every 68 of the city's population cared for in private institutions at the public expense. The report quotes at some length passages from "American Charities" by Amos G. Warner, pointing out the evils of institutional life for young children, and emphasizing the necessity of the most careful administration of any institution caring for any considerable number of children of one age. As a guard against caring for children whose parents or relatives are able to undertake the charge, it is proposed to increase the system of inspection by the Examiners of Dependent Children, and to inaugurate the employment by the institutions of one visitor for every 500 children, whose duty it shall be to examine into the ability of parents or guardians to take partial or entire charge of their children or wards.

It is provided that no payments shall be made for inmates of any private charitable institutions unless the same shall have been accepted by the Commissioner of Public Charities, as a proper charge against the city, and it is ordered that institutions carrying on industrial enterprises in which inmates are required or permitted to work shall keep records showing the financial results of such work, the methods by which products are sold and whether prices below current or market prices are paid for such products; also, separately, the earnings per capita of inmates wholly or partly maintained by the public funds.

Mr. Coler calls attention to the fact that the New York Medical League has strongly attacked the policy of granting public subsidies to private hospitals and dispensaries, chiefly for the following reasons:

1. That many of the hospitals receiving public money are really business enterprises, the hospitals being merely necessary clinical attachments to medical schools, which would have to be maintained for the proper teaching of students, even if the city contributed nothing to their support, and which are worth more to the medical schools than the cost of maintaining them.

2. That the books of twenty-two hospitals receiving public aid show an annual surplus in excess of the amounts received from the city (*i.e.*, if the city appropriations were withdrawn they would still have balances to their credit).

3. That dispensaries do not exercise proper care in confining their activities to those who are really indigent, but promote pauperism by treating free those who are well able to pay for treatment.

Mr. Coler's report was laid over, and will probably be acted upon at the next meeting of the Board.

CORRESPONDENCE.

THE DIDACTIC LECTURE.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Medical school faculties and university committees are just about to meet to arrange their programs of study for the next scholastic year. The moment seems favorable, then, to present some considerations with regard to the didactic lecture. I was not a little surprised that no one raised his voice in opposition when Dr. Hobart A. Hare of Philadelphia some time ago in the columns of the MEDICAL NEWS saw fit to defend that dear, good, old-fashioned traditional institution in our medical schools.

To tell the plain truth it sadly needs defense, for its quondam supposedly natural defenders, the professors at medical and scientific schools generally, are deserting its standard and openly going over to the enemy; only a few veterans,

old in methods if not old in years, still rally to its defense.

We had the benefit of two pedagogic discussions here in New York City during the Christmas holidays, both of which trenched upon this subject of the didactic lecture in teaching the various sciences. Before the Association of American Anatomists Dr. Holmes of Philadelphia made a suggestion that attracted a good deal of attention and afforded not a little amusement. If the didactic lecture, he said, be considered absolutely necessary a committee of the best professors of anatomy in the country should be selected to draft an ideally compiete and up-to-date set of anatomical lectures which the most taking elocutionist of the Association should talk into a phonograph and then replicas of the cylinders be sent to the various schools for use. If we must have the regular hour's talk so many times a week for the long-suffering medical student then this suggestion is deserving of serious attention.

In the discussion that ensued no one had anything good to say of the didactic lecture. Professor Burt Wilder of Cornell thought it had been and is yet overdone. Professor Gerrish of Portland, Me., thought it still has a place, but a very limited one, and that in a different form and with different aims from those which it is now thought to have. Professor Huntington of Columbia thought that the only place left for the didactic lecture is as a preparation for demonstrations to come, but not as a supposed means of conveying information by itself.

At the joint meeting of the affiliated scientific societies the subject for discussion was advances in methods of teaching science. Dr. Conklin, Professor of Zoology in the University of Pennsylvania, said that the merely didactic lecture is a thing of the past. The value of teaching in science is directly proportioned to its contact with the living sources of scientific progress. Demonstrations and laboratory work with original research even for the undergraduate are the needs of the hour. Dr. Huntington, Professor of Anatomy at Columbia, filling out what he had previously said before the Anatomical Society, declared that object-teaching has replaced theory. Demonstrations, and those to small numbers of students, so that personal attention can be given to each one are the key-notes of the modern method of teaching anatomy. Dr. Porter, Associate Professor of Physiology at Harvard University, outlined a course in physiology in which experimentation had the most prominent place and very little room was left for the didactic lecture, practically none for the lecture as a lecture, but only as a preparation for experiments or sometimes as a historical résumé of the subject. At the end of his paper he epitomized the subject in the following striking manner: "We cannot hope to escape (in this suggestion of reform in medical education) what Bismarck has called the phrase watering-pot. We shall have urged against us certain sanctified expressions such as the accumulated wisdom of centuries. Let us answer that the system by which we now teach anatomy and physiology (may we not insert here, all of medicine?) began as a makeshift and has become a dogma. It is sanctified by some centuries of repetition, not of experience, for systematic experiments in medical pedagogy have rarely been made; the oracles have been severe with those who meddled with the tripod." I think that these quotations at least justify the assertion that it is not merely medical editors who think that the didactic lecture is a thing of the past.

Dr. Hare quotes Professor Hirst's letter in a recent issue of the *Philadelphia Medical Journal*. Professor Hirst's opinion should carry a great deal of weight. His students, I am sure will, without exception, agree with me that he is the most interesting teacher we have ever listened to. He, of all men, should have a right to defend the didactic lecture. This is what he says: "There is, in my opinion, no greater force in medical teaching to-day than the didactic lecture properly given. The lecturer, however, must be able to impart his knowledge to others; he must be thoroughly familiar with the current world literature; he should have every illustration which appeals to him as instructive or interesting reproduced in large size; he should have every instructive case of his own photographed or drawn from life and should have these illustrations enlarged; models should be purchased wherever procurable; specimens should be collected and preserved for demonstration with indefatigable industry, and all this material should be employed to illustrate the lecture. One of my lectures has cost very nearly $1000 for models, pictures, and specimens, and very few have cost less than $50."

Professor Hirst's lectures are not didactic lectures but demonstrations. If the holders of all chairs will illustrate their subjects as unsparingly as Dr. Hirst does his, and take every possible occasion to demonstrate, not to dryly describe, there will be no further need of discussing the didactic lecture.

One of the first lessons in Professor Hirst's course is a demonstration of the coagulum of milk when mixed with rennet. Do any of his students ever forget the flocculent coagulation of human milk, the almost similar coagulum of diluted cow's milk, the thick curds of undiluted cow's milk? One of his last lectures in the course is a demonstration of symphyseotomy on the cadaver. *Satis superque dixi*, there is no need to defend such didactic lectures; they really merit the adjective didactic, for they teach. Though opportunities be invitingly open for the illustration of lectures as Professor Hirst suggests how few of them are taken. Many professors do not seem to have interest enough in their courses to even prepare suitably the current lectures, let alone plan for future ones.

Professor Hare thinks that the popularity of lectures upon history, literature, art, and travel attests the fact that people enjoy and learn much by attending them. As to enjoyment it may pass, though I think the allusion unfortunate since there is nothing in the world less enjoyable than the didactic lectures delivered in most medical schools. It is only a lofty and sadly mistaken sense of duty that brings students to most of them at all. As to what is learned from *popular* lectures the educational world is pretty well agreed that a certain amount of information, often of a most useless, disconnected, and undi-

gested kind, is gained, a heap of conceit is accumulated and a supposed scientific or other basis obtained on which to build the most inane theories if any attempt is made to develop or apply the knowledge thus acquired. A lecture is well enough to communicate a few interesting facts whose acquisition may be displayed brilliantly in conversation, but think of teaching a man to build a locomotive, or the still greater absurdity of fitting him to repair one, by a series of lectures!

Finally Professor Hare thinks that there is no better stimulus than to follow the lecture courses of certain men, and mentions two honored names that will ever stand out in the annals of American medical pedagogy, Agnew and DaCosta. These and such as these are the exceptions that occur to every rule,—men of the widest learning, of magnetic personality of far-reaching personal influence, and a great gift for teaching. Wherever there are Agnews and DaCostas they will be listened to with interest, but I doubt if even these men themselves, thoroughly in touch as they ever kept themselves with the existing needs of medical teaching, would lecture now as much as they did in their day. Billroth, during his time the most interesting clinical lecturer in Europe, gave up the didactic lecture toward the end of his life, after giving it a very fair trial, because he found he could not interest his students.

This subject of the didactic lecture was discussed at the German Medical Congress at Wiesbaden last April, and as the representative of several American medical journals I gave it special attention because of its present interest to Americans. In the German universities very, very few didactic lectures are given. After the preparatory sciences, anatomy, physiology, etc., have been completed there are no didactic lectures on which attendance is compulsory. The state of opinion regarding them is very clear. A few of the old men like Von Ziemssen of Munich still think a regular course of didactic lectures desirable. Most of the old men, however, do not give didactic lectures and it is their influence that keeps the lectures from having an important place in the universities. All of the young men seem to agree with Von Jaksch, who takes high ground against the didactic lecture.

Didactic lectures are still popular in France, but they are very different from what we know as the didactic lecture. They are finished studies, in a classic style, of some up-to-date subject in which all the recent material is accumulated, the newest theories discussed, the conclusions on doubtful points suggested, the probable future development of the subject outlined. Read Professor Raymond's lectures on the muscular dystrophies, or Landouzy on serum-therapy, or Marie on nervous diseases, especially on tabes; or Widal's lectures (if they are published) on pericarditis, or Debove on any subject, and the realization is not long in coming that there is a place for these didactic lectures. They really show that familiarity with the current world literature which Professors Hirst and Hare demand, but such lectures in regular courses are delivered nowhere outside of France.

The subject of medicine has become so vast that it is folly to attempt to teach all its infinite details even to the most willing medical student. The idea of pumping into him by means of the didactic lecture a mass of information that he has not the time to digest and assimilate and then expecting him to apply it practically is a serious mistake—it is more than that, it is a mortal sin against the good rules of modern pedagogy. President Eliot of Harvard has well said, "We must educate for power, not for information." We must train people in habits of scientific investigation, train them in the exact scientific method, train them so that they may develop themselves, not load them down with infinite details of too often useless information. In the other sciences this ideal is being realized more and more. The last few years have seen great advances along these lines in the teaching of the medical sciences. It has seemed to us on the outside, however, as though the progress of reform in the teaching of medicine is impeded by the interested motives of certain professors who foresee their occupation gone if once it is generally conceded that the didactic lecture is a thing of the past, or who realize that much more time will be demanded of them, that the newer methods must be learned, that their ease and comfort will be seriously disturbed, and that the present convenient method of thinking out in the ten minutes that one spends in his carriage on the way to the lecture-room what is to form the mental pabulum of some hundreds of students for an hour or more must be given up for hours of serious thought and reading on what is latest in medicine and on how best to advance the teaching of medicine.

JAS. J. WALSH, Ph.D., M.D.
1973 SEVENTH AVENUE,
NEW YORK, September 9, 1899.

OUR LONDON LETTER.

[From Our Special Correspondent.]

MOSQUITO EXPEDITION — POSSIBLE VALUE OF "CAUSTIC" ETHER RAYS—NEGLECT OF PATIENTS IN POOR-HOUSE INFIRMARIES—NEW BUILDINGS OF WOMEN'S MEDICAL COLLEGE—HUMAN VERMIN IN THE PARKS—PRACTICAL ACTION AGAINST STREET NOISES.

LONDON, September 6, 1899.

THAT sturdy little product of "individualism" the Liverpool School of Tropical Medicine has scored another triumph over its cumbrous state subsidized rival and predecessor, the London (Government) School. While the latter is not likely to be in a position to do anything but ask for more money for a month or more yet, the Malaria Expedition of the former has wired back its discovery and identification of the "criminal" species of mosquito (*Anopheles claviger*) and the mapping out of the breeding-places. By the very next steamer another investigator, Dr. Fielding Ould, with additional equipment, will be despatched by the School to reinforce the original party of five. It is to be hoped that the Colonial Office, now that the Anopheles "hare" has been "caught" by private enterprise will have the energy to send out a few experts to help to "cook" it.

A most interesting suggestion has been made by Mansell Moullin in his Presidential Address before the Roentgen-Ray Society in regard to the "caustic" and

destructive rays given off by the radiating bulb. These so far have simply been a source of annoyance by the destruction and almost escharotic changes produced upon the skin of the patient, but the speaker was inclined to believe that in the future they would come to be regarded entirely apart from the X-rays which they accompany as a valuable addition to our therapeutic agents. The powerful catalytic changes which they are capable of setting up in the surface-tissues exposed to them ought, when properly controlled and understood, to prove of yeoman service in the treatment of various skin affections, including lupus and superficial ulcers, especially of infectious origin.

These ether rays are entirely distinct from the true Roentgen rays, and screens which are perfectly pervious to the latter can be used to shut them off completely, so that as an obstacle to future skiagraphic work they can be completely avoided.

The existence of a "Roentgen-Ray Society" among medical men and physicists certainly strikes one as one of the specialist specializations of specialism. No doubt its existence is fully justified in view of the magnificent possibilities of usefulness of the new-found agency and the need for cooperation of several distinct classes of workers in their development but we trust it will not be regarded as a precedent and followed by "sphygmograph Societies", "Cystoscope Clubs" or "Apostali Associations."

Another revolting illustration of the natural callousness and brutality of officialdom if left to itself has just been furnished from Stepney Union Workhouse. Two deaths under suspicious circumstances having occurred within two days, a coroner's jury investigated the matter. The first case was that of a boy aged nine suffering from tuberculous diarrhea. On Saturday afternoon his father came to see him and was informed that he was asleep and he must sit quietly beside the bed without waking him. The poor fellow did so for nearly half an hour when on looking more carefully at his boy, he found to his horror that he was dead. The nurse alleged that she had seen the boy "apparently asleep" only about ten minutes before the father came, but as it developed that she and one other nurse had charge of 100 patients scattered through six wards day and night, it may be imagined how closely each individual case could be attended. The coroner stated that at a former inquest from this institution some years ago, it was discovered that there was only *one* nurse for 800 patients! Now there were six and he thought that at this rate the institution might become a model one in the year 2752 A.D.

The other case was that of a coal-porter, aged 48, who in the delirium of pneumonia had been put in a *straitjacket and tied down with two sheets* for twelve hours, at the end of which time he, not unnaturally, died of "heart-failure due to exhaustion." No doctor had seen him for thirty-six hours before his death as the intelligent attendant felt sure he "was going to die, anyhow." And we are sorry to say that the action of the medical officer calls for prompt explanation of some sort, as all he did for the patient, by his own testimony, at his first and only visit to him, was to order him *into the padded room*, as "it was impossible to administer a sleeping draught" (?)! From this interesting chamber the patient escaped because "*the door was away for repairs.*" We must confess we think the coroner's estimate of future progress in Stepney workhouse too hopeful.

The new buildings at the London School of Medicine for Women, in connection with the Royal Free Hospital, are rapidly approaching completion. The first wing was finished about a year ago and the second is now nearly ready for occupancy, while the third will be built during the coming year. As the school crowded 190 students last year into its one wing and the old remodeled private house in which the school has held its sessions for twenty-four years past it would be seen that the new buildings are badly needed. Nearly $90,000 has been expended upon the building and $60,000 more is needed to complete it.

The prolonged hot, dry weather in London has rendered one public service in aggravating to a point beyond further toleration a nuisance which has been gradually growing and spreading in London for some years past, and this is the invasion of the public parks for lounging, eating and sleeping, day and night, by tramps, "bums," scalawags of every description, male and female. Greasy, filthy, blear-eyed and red-nosed, these unclean beasts may be seen sleeping off last night's stale-beer orgie upon the benches and the grass of almost all the West End parks, with a special preference for the quiet corners and most secluded nooks, where they utterly destroy the beauty of the scene and sweetness of the air. Swarming with vermin and reeking of the two and seventy smells of Cologne, they are an insult and a source of possible infection to every child or woman who enters the park. This is unpleasant enough for adults, but when we remember that Regent's, Primrose Hill, Battersea, and even aristocratic Hyde Parks are the sole exercise-grounds and breathing space of thousands of children of all ages, some with, but the vast majority of them without, nursemaids other than their elder sisters—who ought to be perfectly secure in sitting, rolling, tumbling, and playing upon the green grass it becomes a nuisance bordering upon an outrage. And in no other city than London would it be tolerated for a week, but these vagabonds be free men and British subjects and all such have a right to use and frequent public places.

Now, however, that they have taken to using the parks these hot nights as sleeping places, leaving the grass greasy with their filth and strewn with broken victuals the patient public is showing signs of getting roused and something decided will be done.

Of course, every possible precaution should be taken against interfering in any way with the full and free use of these "Lungs of London" by the poorest of the poor, no matter how shabbily dressed so long as decent and clean, but there ought to be no practical difficulty in drawing up some sort of an ordinance which will give the police power to exclude tramps and vagabonds, of unclean, disreputa-

ble and offensive appearance and odor, a mere handful of whom destroy the comfort, interfere with the enjoyment, and are a source of danger to the health of hundreds of children, to say nothing of women. The mere sight of one of these creatures is enough to spoil all enjoyment of that part of the park for sensitive women and the thought of their previous occupancy of a seat is enough to deter most ladies from making use of it, no matter how fine the day or how tired of walking they may be.

The much-talked of crusade against street noises and their maddening wear upon the modern nervous system has at last found its paladin. Admirable, if a little strenuous, in theory, it has till now lacked the man of action, the Boulanger who could put himself at its head and lead on to victory. Now, however, he has arrived. His name is George Sims, journalist, of Clerkenwell, and in this manner has achieved immortality. A "mission-service" being held in the street before his windows, he endured the sonorous bray of the invocation, the thin, musical agony of the hymn, and the fierce, nasal chant of the preacher till he could bear it no longer. Out he rushed like a lion roused, knocked over the lamp and sat down violently upon the harmonium. Like most other reformer-heroes he landed in the police court. Here, alas, his confidence in his mission failed him and instead of proudly avowing his act and glorying in the noble impulse that led to it, he took refuge in most inartistically unprobable excuses. He went out to ask the preacher to stop and in the dark fell against the harmonium and accidentally knocked over the lamp. However, the story, tame as it was, "worked," for the magistrate accepted it as gospel truth, discharged Sims and expressed his sympathy with him in his endeavor to "suppress noisy persons." From which we infer that he must have sat upon the preacher as well as the harmonium. Though possibly the wish is father to the thought. Nor was this all, for the court went on to comment severely upon the harmfulness of unnecessary street noices, even though of a religious character. These he denounced as "intolerable and a mistake . . . their intentions are good, but they do not benefit mankind under the circumstances," and with this dictum we think all physicians will cordially agree.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Regular Monthly Meeting, Held May 27, 1899.

THE Vice-President, DR. WILLIAM B. COLEY, in the Chair.

The first paper of the evening was read by DR. EUGENE FULLER, and was entitled

SOME POINTS ON VESICAL NEOPLASMS.

It is only within the last few years that vesical neoplasms have received much attention. Neoplasms of other organs, because more frequent and more readily operable, have been the subject of more study. Then the surgery of the bladder, until recent years was discouraging in its results, and anything like radical operation for tumors of the viscus was considered too risky. Present active study is making up for this neglect in great part and we now know that neoplasms of practically all types, benign, intermediate, and malignant occur in the bladder. Here, perhaps more than anywhere else, has come the realization that certain tumors which in the beginning are composed of elements that would cause them to be classed as benign, may degenerate and become malignant.

Papillomata are the tumors originally benign that most frequently take on this degeneration into malignancy. They are easily hurt and a series of traumata almost always brings on malignant degeneration. Their most frequent sites are in the trigonum and around the ureters and they occur most frequently in males. Vesical polyps resemble nasal polyps in many ways, in their structure particularly and in their tendency to recur after removal. Other benign tumors are comparatively rare. Myomata occur especially in fetal remnants of the ducts of Müller. The tumors are often mixed in character containing also fibrous tissue. They sometimes grow to a large size. The mucous membrane may be destroyed above them from pressure, and ulceration results. Only one case of angioma of the bladder has been reported and that by Albarran. When benign tumors occur in the upper part of the bladder operation is easy and the results very favorable, but unfortunately, they usually develop in the lower part of the viscus where operation is more difficult.

Of malignant tumors sarcomata are rare and develop usually in the young and at the base of the bladder. Though the opposite has been said they seem to occur quite as often in females as in males. Other malignant tumors develop at times as the result of irritation. For instance, a number of carcinomata of the bladder have been noted in the employees of a German aniline dye factory. They took their origin about the orifices of the ureters, which indicates the necessity for careful search especially at these points when looking for beginning neoplasms.

The most constant symptoms of vesical neoplasms are hematuria, pain, and incontinence of urine. Hematuria is the most uniform single symptom. It occurs in 90 per cent. of papillomata, in 80 per cent. of sarcomata, in 75 per cent. of carcinomata. There are cases, however, as may be easily understood from these statistics in which it does not occur at all, so that its absence cannot be used to exclude the presence of a neoplasm. Pain is not of so much importance as a diagnostic symptom. Diagnosis is not, however, very difficult as a rule, when the cystoscope is employed.

Once the presence of a vesical neoplasm is suspected, extreme care should be taken as to intravesical examinations, for infection will greatly complicate the course of the case after operation. Fenwick lays great stress on the advisability of not making an intravesical examination until all is ready for operation.

According to the cystoscopic appearance Fenwick gives the following hints for the diagnosis of the character of the tumor: If the mucous membrane is pinkish above it

the tumor is in good condition, and is usually benign. If the mucous membrane is smooth, the tumor is usually superficial. A whitish appearance of the mucous membrane indicates carcinoma and phosphatic deposits on the surface of the tumor point to malignancy.

In operating for tumors of the bladder the suprapubic route seems in every way the most desirable. For certain friable tumors some have thought of intravesical manipulation without incision of the bladder walls. Nitze has suggested this method by instrumentation through a cystoscopic tube, but a certain risk of subsequent hemorrhage exists for which a suprapubic section may have to be done later. Chismore suggested engaging small polypoid tumors by means of suction, which draws the tumor into the tube and enables it to be twisted off. Dr. Fuller has succeeded in this method once, but besides securing very little if at all, against recurrence, there is the dissatisfaction of working in the dark and the risk of subsequent hemorrhage.

The suprapubic operation gives an especially good field for the control of hemorrhage. In severe hemorrhage the bladder may be packed with gauze. The gauze should be put in in numbered slips so as to facilitate its removal, but there is always some shock on taking them out. The ideal operation is to close the bladder entirely, a practice that Guyon and Albarran introduced, and depend for drainage entirely on a catheter *a demeure*.

Papillomata and carcinomata are so liable to recur that it would seem best in all cases to remove with the tumors a portion of the bladder wall. A resection of the bladder is not considered so serious an operation as it used to be. The mucous and muscular layers may be cut with a scissors with serrated edges so as to avoid hemorrhage as much as possible. An elliptical piece may be removed and then the edges brought together. In all the movable parts of the bladder this procedure involves very little difficulty and practically no risk. In the fixed portions of the bladder it is more dangerous and difficult but it may be accomplished successfully, if proper care be taken.

DR. EGBERT GRANDIN, in the discussion which followed, said that neoplasms in the female bladder are rare. Owing to the relations with the vagina, moreover, they are easier to remove. A T-shaped incision in the anterior vaginal wall with the flaps dissected well back gives an excellent field for operative work on the female bladder.

DR. NOEL said that while irritation sometimes leads to malignant degeneration of benign growths of the bladder, it is sometimes true for villous growths especially, that disturbance of them or removal of a portion of them leads to their entire disappearance. Alcoholic injections into the bladder sometimes accomplish this favorable result of making villous growths disappear. In a recent case injections of alcohol of 20 per cent. and finally of 50 per cent. strength were used. Clumps of villous material were passed from time to time per urethram until finally the growths completely disappeared.

DR. COLEY mentioned a case that illustrated very forcibly the change from benignity to malignancy in vesical tumors. A tumor was removed by Dr. Ferguson from a patient in 1894, and on careful examination proved to be a simple papilloma. It recurred and the new tumor proved to be an infiltrating epithelioma of the purest type.

DR. MURRAY said that in the treatment of vesical tumors in women the great dilatability of the female urethra must be borne in mind. He had just had a case under observation of a nurse who had never menstruated and who proved on examination to have no vagina. She had had sexual relations per urethram but without the occurrence of incontinence of urine. It is evident then, that small villous growths might easily be grasped through a urethral speculum, twisted off, and then their bases touched with nitrate of silver.

DR. FOOTE said that recent German statistics of operations for malignant tumors of the bladder show a high operative mortality, and only very few survivals for any length of time after operation, so that the advisability of operation is questionable.

DR. FULLER said, in conclusion, that general statistics condemn operation, but the work of selected operators must be judged on its own merits. It is only the work done at the Necker Hospital, Paris, that is of a sufficiently high order to give encouraging results. Cases of vesical neoplasms are, as a rule, so hopeless that it is better to do something that promises, even though at considerable risk, some relief from present pain and trouble and some prolongation of life than to sit idly by and talk soothingly to the family. The general statistics of prostatectomy are almost as bad as those of the operation for vesical tumors, yet in certain operators' hands excellent results are by no means rare.

DR. HENRY C. COE being unavoidably absent his paper, entitled

SOME NOTES ON THE INDUCTION OF PREMATURE LABOR,

was read by the secretary, Dr. Walker.

The author said that in reading the text-books and listening to lectures on the subject one would be inclined to think that the induction of premature labor is one of the easiest tasks in medical practice. A certain technic must be employed it is true, but if directions are carefully followed it would seem that there would be no difficulty in exciting the pregnant uterus to contraction, and once begun these contractions made to continue until the uterus is emptied. When it comes to actual practice in this matter there must certainly be some rather disagreeable and disappointing developments as to the ease with which premature labor may be brought on.

Gynecologists generally know now that the pregnant uterus will tolerate without reaction sufficient to produce abortion, an amount of tampering with that would have been thought utterly incredible some years ago. The author related some recent cases in his experience that illustrated this fact.

CASE I.—A multipara, pregnant for more than four months, developed a large abscess behind the uterus. Peritonitis set in and there was high temperature for several days. On laparotomy so many adhesions were

found that the abdominal incision was closed and the abscess drained per vaginam. Quite an amount of offensive pus escaped and hydrogen peroxid and gauze drainage were employed. Despite the surgical manipulations, the presence of the gauze and the occurrence of peritonitis and fever, abortion did not occur at this time but more than a month later when the woman was up and about.

CASE II.—Multipara; pregnant five months. In this case an adherent cyst of the ovary became twisted, and intracystic hemorrhage and beginning necrosis resulted. At the laparotomy the uterus was lifted up and surrounded by hot towels. The operation was much longer than was at first anticipated and sutures had to be taken in the broad ligament and in the peritoneum covering the uterus. The case ran an absolutely afebrile course and no symptoms of abortion supervened. The patient was up and about feeling perfectly well in four weeks. Fetal movements were very active and could be easily felt and seen by the examiner.

CASE III.—Multipara; pregnant four months. Very similar to Case II. An adherent dermoid was removed from Douglas' pouch without producing the slightest uterine reaction. The patient carried her child to full term and had a normal labor.

As a matter of fact, however, these cases of operative intervention involving at least indirectly the pregnant uterus yet without setting up labor pains have become so common of late years that they no longer attract much attention. They serve to show very well the tolerance of the uterus in most cases.

In text-books it is often said that dilatation of the cervix is very liable to be followed by abortion. Nearly every gynecologist has more than once dilated the cervix for obstinate vomiting without producing any such effect. The author never has had abortion occur in his practice from this cause, though he introduces the branched dilator and separates the blades to their fullest extent. In fact unless the membranes are ruptured at the same time he does not think abortion is liable to take place.

The introduction of a bougie is sometimes stated as sufficient to induce labor pains. He quoted a case in which the introduction of a sound followed by intra-uterine faradization failed to produce the slightest effect, and the cervix had to be forcibly dilated and active removal of its contents proceeded with.

The use of Barnes' bags and of the gauze tamponade are the other methods usually mentioned for producing abortion. The bags seem to be going out of fashion of late, at least we do not hear as much of them at society meetings as we used to. The author said that he had had cases, however, in which neither gauze nor bags (nor sometimes both) produced satisfactory labor pains, and the manual or instrumental delivery of the child had to be undertaken after their unsuccessful employment. While they did not bring on labor pains they did produce a dilatation of the cervix that was of the greatest service in the subsequent manipulations.

CASE I.—A multipara. Various sizes of Barnes' bags were introduced and finally the double McLean bag, which the author had often found useful. Some transient pains resulted but without the desired effect of inducing labor. After thirty-six hours of waiting manual dilatation was performed. It was greatly simplified by what had been accomplished by the bags and healthy twins were delivered by podalic version.

CASE II.—Multipara. Three yards of gauze was first packed within the os internum, and then increasingly large sizes of bags were used. Absolutely no pains occurred though cervical dilatation was perfect so that at the end of forty-eight hours manual extraction was carried out and proved very easy.

CASE III.—Multipara. First gauze was inserted and left for twenty-four hours without effect. Then bags were used and left in as long but with the same result. Then manual dilatation had to be done, but as usual after the use of the bags and gauze, was easy of accomplishment. Mother and child both did well.

CASE IV.—Multipara. More than four yards of gauze was inserted into the lower uterine segment. No reaction took place in twenty-four hours; then a large double bag was inserted but effective labor pains were not induced. Manual extraction was extremely difficult in spite of the good dilatation that had been effected. In another case at the fourth month of pregnancy the insertion of a steel sound and then of two yards of gauze produced no effect, not even dilatation, and the uterus had to be emptied manually.

These cases show that as a rule the Barnes' bags and the gauze tamponade are useful in producing softening and dilatation of the cervix, but they often do not bring on effective labor pains. It would seem better then, after these means have been tried without result for thirty-six hours, that the obstetrician should proceed actively to empty the uterus rather than keep the patient and her friends any longer in suspense.

In the discussion DR. MURRAY said that there is no need to excite labor pains, and that in fact rapid extraction can be accomplished better without them especially under an anesthetic. Personally he has been very well satisfied with the effect of a steel dilator and then the Barnes' bags to soften the os. He can tell the time at which he will be able to empty the uterus as exactly as he is able to appoint the time for a laparotomy. For uremia or persistent emesis he dilates under anesthesia with successively larger steel bougies until two fingers can be inserted. He then employs placental forceps, taking special precautions to see that the cornua of the uterus are thoroughly emptied. In a recent case, in a doctor's wife, he employed forcible rapid manual dilatation with excellent results. First one finger was inserted in the os, then gradually the cone-shaped fingers were forced in. After three-quarters of an hour sufficient dilatation was secured and a child weighing 15¾ pounds was delivered alive. He does not believe in the use of gauze but thinks Barnes' bags of great value especially in placenta previa.

DR. GRANDIN said that he was glad to find that the cobwebs of a too insistent tradition are being brushed away from certain important practical medical subjects. In no branch of medicine does tradition count for more

than in obstetrics and in no question does it cause more hesitation as to the proper course to be pursued than in this one of inducing premature labor. There is no need of complicated instruments or apparatus.

Dilatation of the cervix can be produced manually in half to three-quarters of an hour. In placenta previa 85 per cent. of the women and 66 per cent. of the children are saved by this method and there is no other that gives anything like as satisfactory results. The cervix yields to the fingers somewhat as the sphincter ani does, and only patience is needed to secure an entrance. A danger that must always be looked for is post-partum hemorrhage and for this a large gauze pack is necessary. At least ten yards of gauze two inches wide should be packed into the uterus and made to completely fill it, if there are signs of hemorrhage and the uterus has not contracted well.

DR. COLEY presented the specimens from a case of carcinoma of the cecum, which showed some interesting features. The patient was operated on for what was thought to be a chronic appendicitis, but at the operation it was found that a cancer of the cecum existed that had been communicated to an adherent coil of small intestine. The whole of the cecum and about five inches of small intestine were removed. The patient made a good recovery. The interest of the case consists especially in the fact that the carcinomatous process had started in the cecum and had invaded the coil of small intestine that had become adherent to it, an example of the communication of cancer to a contiguous viscus that is sufficiently rare to be worthy of special notice.

REVIEWS.

ON FRACTURES AND DISLOCATIONS. By PROFESSOR DR. H. HELFERICH of Greifswald. Translated from the Third German Edition by J. HUTCHINSON, JR., F.R.C.S., Surgeon to the London Hospital. New York: Wm. Wood & Co., 1899.

THE volume before us is one of the Lehmann atlases, which has in past editions of the original received much well-merited praise. The plates are very well reproduced and are very instructive though somewhat diagrammatic. The translation of the text, a condensed outline of the subject, has been well done by Dr. Hutchinson, but some elementary matter has been altogether omitted. The main value of the atlas lies in the plates and their appropriate descriptive text, and for these the volume may be highly recommended to both physicians and medical students.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS AND SURGEONS (Columbia University), New York. Vol. VI.

THIS volume of reprints is taken up mainly by a study on ganglion cells by Dr. James Ewing. It contains, besides, some bacterial studies by Drs. Meltzer and Cheesman, a report of a case of acromegaly by Dr. Bailey, and a readable article on snake poisons by Dr. Langmann.

THERAPEUTIC HINTS.

For Hyperemesis.—

℞	Menthol	gr. iss
	Cocainæ hydrochlorat.	gr. iiiss
	Syr. simplicis	ʒi
	Spiritus	ʒii.

M. Sig. One teaspoonful every half hour.—*Morel-Lavallée.*

Formula for a Creosote Pill.—

℞	Creosoti	parts iii
	Ol. amygdal. dulc. }	
	Sacchari } aa.	parts i.
	Magnesiæ }	

Mix the oil and creosote and rub with the sugar in a mortar. Add the magnesia, mix thoroughly, and let stand for twenty-four hours before preparing the pills.

Paraformaldehyd Collodion in Dermatology.—UNNA recommends this preparation as a caustic for the removal of small cutaneous growths. Paraformaldehyd is not soluble in collodion, but enough is contained in the latter for the purpose indicated. The patient can make the necessary repeated applications himself, as the caustic action is limited and not severe. The area to be covered should be rubbed briskly before the collodion is applied:

℞	Paraformaldehyd	gr. xv
	Ol. ricini	*m.* viii
	Collodii	ʒ v.

M. Sig. External use.

For Herpes Zoster.—

1. ℞ Cocainæ hydrochlorat. gr. iv
Zinci oxidi gr. xvi
Amyli ʒ iiss.
M. Sig. External use.

2. ℞ Ac. borici gr. xxx
Zinci oxidi ʒi
Glyceriti amyli ʒi.
M. Sig. External use.

For Sciatica.—

SIEGRIST of Zürich has found the application of hot moist compresses to afford striking relief in this affection. A piece of flannel is placed in very hot water, then taken and wrung out so that it does not drip. This can be done conveniently by wringing it inside a towel in such a way as to protect the hands. The flannel is then laid along the thigh of the patient—if the skin is very sensitive a layer of flannel is placed under the compress—and the whole covered with several thick layers of dry flannel. The compress is changed in about ten minutes, and the process kept up for an hour or two at a time, and repeated several times a day. The value of these fomentations in many painful affections is well known to students of hydrotherapy, but is not sufficiently recognized by physicians in general. The treatment demands considerable time, and must be skilfully executed in order to gain the desired results.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, SEPTEMBER 23, 1899. NO. 13.

ORIGINAL ARTICLES.

THE BACILLUS ICTEROIDES: A REPLY TO DR. SANARELLI.

BY F. G. NOVY, M.D.,
OF ANN ARBOR, MICH.;
JUNIOR PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

IN the issue of the MEDICAL NEWS for August 12, 1899, Dr. Sanarelli has endeavored to controvert various statements made by myself and others relative to his bacillus icteroides. No one can object to his taking such action, but it is to be regretted that he believes a personal element has obtruded itself into the controversy "as a result of the attitude assumed by Dr. Sternberg," or any one else. Actuated by this belief my eminent colleague has abandoned himself to a mode of thinking and a style of writing which is deservedly questionable in a great discoverer. A scientific publication is open to doubt and criticism as well as to unquestioning acceptance. This is especially the case when such publication does not carry within itself a complete and perfect chain of evidence.

A study of the several lengthy and painstaking memoirs published by Dr. Sanarelli failed to convince me as to the correctness of his claim and it may not be out of place to remark that some workers in other countries have formed similar conclusions. Thus, Professor Carl Fraenkel of Halle, commenting upon the investigations of Foà and of Sanarelli (*Hygienische Rundschau*, p. 1000, 1898), expresses his grave doubts as to whether the bacillus icteroides is really the cause of yellow fever. More recently, the same authority (*Ibid.*, p. 633, June 15, 1899) expresses himself to the effect that my conclusions agree fully with his views. Similar doubts as to the validity of Dr. Sanarelli's claim were expressed in France by Thoinot who questioned whether the Sanarelli, as well as the Havelburg, bacilli were not strangers to the production of the disease (*Annal. d'hygiéne Publique*, 38, p. 172, 1897). Dr. London of the Institute of Experimental Medicine at St. Petersburg, while agreeing that the bacillus icteroides is a new and interesting organism, preferred to leave open the question of its etiological relation. I mention these facts in order to show that Dr. Sanarelli's memoirs did not furnish a satisfactory proof of the correctness of his conclusions, and, that, therefore, criticism could be properly made without being actuated by other motive than a desire to arrive at the simple truth.

The resistance of the bacillus icteroides to cold has seemed to me to be incompatible with its supposed role as the cause of yellow fever. I take it to be an established fact that yellow fever does not spread in cold or freezing weather. Dr. Sanarelli cites Corré to show that in Baltimore and Philadelphia more than a hundred persons a week were carried off by the disease in November and December while the temperature was at times below zero. How well this is substantiated may be seen from what follows: The history of the early epidemics is by no means always clear either as to the date of their extinction or as to the exact temperature prevailing at such time. Nevertheless, such a painstaking writer as La Roche fails to substantiate the above statement as to the weekly mortality during the months of November and December. According to Rush the epidemic of 1699 disappeared by the end of October or the beginning of November ("Medical Inquiries," 3d ed., vol. iii, p. 187, 1809). The yellow fever of 1741 was arrested by cold (La Roche, l., p. 56); that of 1747 persisted into October, but on the 16th of that month Franklin wrote that it was "almost if not quite over" (*Ibid.*, p. 60). The epidemic of 1762 was arrested by the accession of winter (*Ibid.*, p. 61), and according to a letter written by Dr. Redman in 1793 it appears that the disease in 1762 declined rapidly during the first part of October, and as a result he had no yellow-fever patients after the first week in November.

With reference to the epidemic of 1762 it may be well to quote from Rush (*loc. cit.* 3, p. 188) a passage which apparently does not agree with the preceding statement. He says: "I have in vain attempted to procure an account of the time of the commencement of cold weather in the autumn of 1762. . . . I have said that it continued to prevail in the months of November and December. The register of the interments in the Friends' burying-ground in these months confirms that account. They were nearly as numerous in November and December as in September and October, *viz.*, in September 22, in October 27, in November 19, and in December 26" From this statement of Dr. Rush, which is contrary to Redman, who in 1762 was his

teacher, it appears that the disease did prevail in November and December, but in the absence of any information as to its exact nature, and as to the prevailing temperature the supposition is justifiable that, if yellow fever, it persisted during an extremely mild period.

In the great epidemic of 1793, 1976 persons died during October, while the mortality in November was only 118. The disease ceased entirely by the close of the first week in November (La Roche, I., p. 68). According to Rush (vol. iii, p. 266) yellow fever prevailed in Philadelphia during the winter of 1794 and spring of 1795, "the weather being uncommonly moderate." In ten months he treated some 200 patients, and lost only 4 (*loc. cit.*, p. 421). It is hardly necessary to state that most of the physicians of the day did not agree in this diagnosis. The occurrence of a doubtful disease during the winter months of 1762 and 1794 cannot overthrow the conclusion which all other epidemics substantiate. The outbreak of 1797 was checked by the advent of winter frost which occurred at an earlier date than in 1793 (La Roche, p. 79). Finally, in 1798, yellow fever in Philadelphia caused the death of 942 persons in October, while only 110 deaths occurred in November, and most of the victims apparently died in the first week of that month. Indeed, the epidemic was declared to be at an end on November 1st (*Ibid.*, p. 84).

According to the eminent writer, Hirsch, "a frost has brought the epidemic to an end under all circumstances whatsoever" (vol. i, p. 351). Another historian, Haeser, arrives at a similar conclusion when he states that "an epidemic may continue at a low temperature, but it is surely terminated by the appearance of a real frost."

To still further invalidate my objection as to the behavior of bacillus icteroides to cold, Dr. Sanarelli refers to examples of vessels which, infected with yellow fever, were frozen up in Arctic ice for months. I am aware of one instance of this kind, that of the U. S. S. "Plymouth," which had a not very convincing experience for a few weeks with "Arctic ice" at Boston. The vessel in question, after developing yellow fever on board, sailed on November 7th from Santa Cruz for Norfolk where it was repeatedly fumigated, and the clothing and bedding of the sick were sent ashore. The ship then proceeded to Portsmouth, N. H., where it was quarantined for seventeen days, after which it was taken to Boston. On January 8th, the crew *with their clothes and bedding* were transferred to a receiving-ship. For about five weeks all parts of the ship were exposed to intense cold, which at times was below zero. In addition 100 pounds of sulphur were burned below deck, and the berth-deck, holds, and store-rooms were thoroughly whitewashed with lime and chlorid of lime. On February 12th the crew returned to the ship, which sailed on March 15th for the Windward Islands. While still at sea, on March 22nd, yellow fever appeared and the ship was obliged to return northward. Thus, in spite of the great cold, of fresh air, fumigation, and whitewashing, the disease was not eradicated. The Board of Medical Inspectors reported that the virus of the disease must have been preserved in the rotten wood of the berth-deck, *or in the bedding and clothing of the crew* (*Sanitarian*, vol vii, p. 348, 1879). These articles, it seems, were not disinfected or exposed to cold, and it is more than likely that in this way the disease germs escaped destruction. That the yellow-fever organism may retain its vitality in clothes for many months was shown by the Madrid epidemic of 1878 (Hirsch, vol. i, p. 374), and a similar instance is reported by Bell, (*Sanitarian*, vol. xxi, p. 506), who attended a case of yellow fever in New York originating from infected clothes which were shipped three months before from New Orleans.

It cannot be denied that there have been instances, in Spain and in this country, in which the yellow-fever organisms have apparently survived the winter and, with the oncome of warm weather, have given rise to a renewal of the epidemic. This recrudescence of the disease is observed, however, only after a very mild winter. Exceptionally, it may be due, as in the cases mentioned above, to infected clothing or bedding which may have been stowed away during the winter months.

It is true that many epidemic diseases like cholera, pest, etc., diminish in virulence, and often almost disappear with the advent of cold weather. There is, however, this to be noted, that, while epidemics of yellow fever have never been known to occur in midwinter, outbreaks of cholera and pest in the coldest season have not been uncommon. It may be sufficient to cite as an illustration the cholera epidemic at Nietleben (January-February, 1893) where in spite of the coldest season the relative mortality was greater than at Hamburg in the preceding summer (Koch, *Zeitschrift f. Hygiene*, 15, p. 90). The severe outbreak of pest at Vetlianka, on the lower Volga, October, 1878—January, 1879) is a notable reminder of the fact that in the past the bubonic plague has frequently prevailed during the coldest weather.

Midwinter epidemics, such as those referred to, lead to the natural inference that the specific germ in each case is resistant to extreme cold. Hence, it is not surprising that pure cultures of cholera, pest,

and typhoid fever, should show little or no result on exposure to low temperatures. The experiments along this line are well known, and have served to establish the general proposition that cold, unlike heat, does not destroy bacteria. It is safe to say that every law has its exceptions. Dr. Sanarelli, however, would believe that because cold does not destroy the common well-known bacteria it is without effect on all bacteria. When Dr. Sanarelli asks for a single specific pathogenic germ which is not capable of enduring a low temperature he surely overlooks one that is of no little importance. This is the gonococcus which according to Christmas ("Annales de l'Institut Pasteur," vol. 11, p. 616, 1897) "*is killed in a few hours if the temperature descends below 15° F.*" The gonococcus is a striking exception in the behavior of bacteria to cold and it is obvious that others may exist.

There are several theories that can be proposed to explain the complete extinction of yellow fever by the advent of cold. It may indeed be that the assumption that cold acts directly by destroying the specific germ is incorrect, but, for the present, it explains well-known epidemiological facts better than the theory of inhibition of growth which it is difficult to uphold in the case of midwinter epidemics of cholera and pest.

The behavior of the bacillus icteroides to cold together with the incomplete evidence offered by Dr. Sanarelli rendered its relation to the disease very doubtful. I am free to acknowledge that since then the evidence in favor of this organism has been strengthened by other investigators. Inasmuch as these did not publish their results prior to the appearance of my paper I cannot be said to have ignored, or to be ignorant of current literature, as Dr. Sanarelli courteously remarks.

The criticism which Dr. Sanarelli makes as to my agglutination experiments apply really to his own work and not to mine. My experiments were intended to show that serum reactions made in a test-tube with dilutions of only 1 to 5 or 1 to 10, as practised by him, were without value. When he now states that the serum dilutions should be always at least 1 to 40 he merely confirms my conclusions as to the value of his agglutination test. Ordinary perusal of the part on agglutination will show that I describe the method employed, which the familiar reader will recognize to be that recommended by Widal, and that I give the degree of dilution of normal serum at which agglutination ceases.

A similar condition of precipitancy pervades the discussion as to the production of toxin and antitoxin. I have shown that the filtered culture did not possess a powerful toxin such as would exist if Dr. Sanarelli's theoretical considerations, which it is unnecessary to recapitulate, held true. The fact that Dr. Sanarelli himself failed to obtain an antitoxic serum ("Annales de l'Institut Pasteur, 12, p. 349, 1898) corroborated my own results. If, therefore, Foá has succeeded in preparing an antitoxic as well as anti-infectious serum he has done what both Dr. Sanarelli and I have failed to do.

I am greatly surprised that Dr. Sanarelli should so misconstrue my statement that the bacillus icteroides "produces in experimental animals a disease not unlike that following infection with the bacillus coli commune," as to believe that I impugn either his good faith or good judgment. Although he has not seen fit to credit others with either of these attributes it has never occurred to me to take such a course. The statement referred to does not lead to the inference that the bacillus icteroides and bacillus coli commune are identical. I think I have made it clear elsewhere in my paper that the two organisms are different, and that it is an easy matter to distinguish one from the other. I may add further that in my "Laboratory Work in Bacteriology" (p. 356) I describe fully the bacillus icteroides which I certainly would not have done had I believed it to be identical with the bacillus coli. The changes induced in animals, however, are very much alike, and in this view I am supported by Drs. Wasdin and Geddings, who state that "the same or very similar results were obtainable by the use of other organisms of different kinds," and that when animals were inoculated with bacillus icteroides, bacillus *x*. and Havelburg, and coli commune "necropsies upon these revealed similar conditions of the organs" ("Public Health Reports," No. 33, p. 1305, 1899).

The latest studies on yellow fever may have revealed the presence of the bacillus icteroides in most of the cases examined. I am not aware, however, that Dr. Geddings has isolated it in seventy-nine cases. In his preliminary report ("Public Health Reports," No. 45, p. 1272, 1898) he tabulates his results showing that of sixteen cultures examined, not cases, thirteen were positive. In the abstract of the final report (*Ibid.*, No. 33, 1899) Drs. Wasdin and Geddings report upon twenty-two cases. They concurred in the diagnosis of fourteen of these, and succeeded in isolating the bacillus icteroides from each of these cases, but failed in the remainder. Evidently a slight error has crept into this statement.

The recent detection of the bacillus icteroides in a considerable number of cases of yellow fever, and, moreover, its probable absence in other diseases has given this organism a much needed support. Per-

sonally, I shall be pleased if the final report of Drs. Wasdin and Geddings will furnish incontrovertible evidence as to its specificity. Such is my attitude on this important question, and as a seeker of truths I trust I may ever be open to conviction when indisputable proofs are offered.

INOCULATION THROUGH THE DIGESTIVE TRACT: A CONTRIBUTION TO THE YELLOW-FEVER DISCUSSION.*

By FELIX VITALE, M.D.,
OF COYTESVILLE, N. J.;
FORMERLY LIEUTENANT-SURGEON IN THE ITALIAN ARMY; EX-FORENSIC PHYSICIAN TO THE CITY OF MONTEVIDEO, URUGUAY.†

THE discussion as to the relations between the bacillus of hog cholera and Sanarelli's bacillus icteroides has attracted a great deal of public attention of late. The settlement of the points at issue in the matter rests to a large extent on the question of inoculation of infectious material by way of the digestive tract. It has seemed to me opportune, then, to discuss the question of the difficulty of inoculation by this method, and the true value of experimental results obtained in this way.

In his recent answer to Sanarelli[1] Dr. Sternberg insists on the serious significance of the results obtained experimentally by Drs. Reed and Carroll[2]. These observers noted in the case of three hogs the characteristic lesions of hog cholera after they had fed the animals on warm cultures of bacillus icteroides. In a more recent article (MEDICAL NEWS, September 9, 1899) Drs. Reed and Carroll themselves reaffirm their former conclusions as to the identity of lesions produced by the bacillus of hog cholera and by the bacillus icteroides when inoculation takes place through the digestive tract. On the other hand, Drs. Wasdin and Geddings[3], having employed exactly the same experimental method, reach directly opposite conclusions. They say, first, that the domestic hog is incapable of infection from the bacillus icteroides when the latter is introduced through the intestinal or digestive tract; and, second, that the bacillus icteroides when fed to pigs will not produce any of the lesions or intestinal symptoms of hog cholera.

I think that I shall be able to show a little farther on that Dr. Sternberg's declaration on the strength of the researches of Drs. Reed and Carroll that the bacillus icteroides and the bacillus choleræ suis are practically the same micro-organism is made without sufficient evidence. As far as regards the anatomical lesions observed by both parties, however, though it may seem a paradox to say so, I believe that both may be perfectly correct in their declarations, though I hold that Wasdin and Geddings are surely right in their assertion that the infection of the domestic hog in their experience is impossible by the method pursued of feeding the bacillus icteroides to the animal.

It is an elementary principle in bacteriology when there is question of the inoculation of pathological material or of bacterial cultures that after the selection of an animal that presents the greatest susceptibility toward a given infectious material, the next most important thing is the determination of the best mode of entrance of the latter into the animal tissues. How important this matter of the "best port of entry" is may be judged from certain well-ascertained facts. The staphylococcus, for example, inoculated beneath the skin of a guinea pig produces nothing more than a local abscess, while injected subcutaneously it produces a fatal pyemia. Tuberculosis pursues a very different course according to the various regions into which it may be inoculated. Chaveau and Arloing were able to inject with impunity as much as 162 c.c. of a culture of a septic vibrio directly into the vein of a dog, while a few drops of the same culture injected under the skin infallibly killed the animal.

At a time that is not very long past inoculation by way of the digestive tract seemed the most obvious thing in the world. It was even believed that many microbes found their way into the system by the mouth. But at the present time, on the contrary, the comparative study of microbes and of the constant struggle for life going on among them in certain of their habitats has demonstrated that inoculation by the mouth, apparently the simplest mode of infection, is in reality the most difficult and complicated. For the bacteriologist who would inoculate through the gastro-intestinal tract there is a series of obstacles that he must overcome which, so far, bacteriology has not succeeded in entirely getting rid of. There is the digestive activity of the gastro intestinal tract itself, the predilection of the microbe very often for the intestinal contents rather than the tissues, the failure of receptivity on the part of the animal to a given microbe at a given moment, and finally the influence of the microbic flora already present in the intestine.

Koch administered opium to his animals when inoculating with the cholera vibrio by the mouth because it paralyzed the gastro-intestinal activity, or he gave them alcohol in order to set up a gastro-intestinal catarrh, and so lessen the vital resistance of the tissues. Emmerich did the same thing when

*Translated.

†Dr. Vitale was a student with Professor Sanarelli at Montevideo, Uruguay, at the time the latter was carrying on the investigations which resulted in the announcement of the discovery of the bacillus icteroides.—Editor.

experimenting with his bacillus Neapolitanus. Metchnikoff, besides the two methods already mentioned, alkalinized the gastric juice. Notwithstanding these precautions, the results in all of these experiments were often inconstant. The question of the lack of receptivity needs but to be mentioned, and the same holds true of the predilection for certain materials.[4] Strauss fed the sputa of tuberculous patients in large quantities to hens without a single one of them acquiring tuberculosis, and we know that it would be absolutely useless to attempt to inoculate a bacillus such as that of Nicolaier by the mouth, for even when inoculated beneath the skin it needs the assistance of certain microbes that favor its growth by overcoming for it the resistance offered at first to its invasion by the phagocytes.

The antagonism, vital as well as chemical, of one set of microbes for another deserves even more attention than any other factor which prevents their invasion of the animal organism if we would understand the reasons for the failure of inoculations by way of the digestive tract. Kitasato first called attention to this subject but Metchnikoff's experiments are so much more complete that we shall quote from them. Metchnikoff[5] inoculated plates of gelatin with the vibrio of cholera. The following day, after noting that none of the plates showed the presence of any culture, he exposed some of them to the air, and inoculated the surface of the others with various microbes. Some of the microbes implanted later favored while some hindered the development of the cholera vibrio, while others completely destroyed it and prevented it from growing.

He noted in subsequent experiments that certain microbes were able to prevent the growth of the cholera germ, not only in their own vicinity under ordinary circumstances, but even when it was growing along with a microbe that usually favors its growth. For instance, a plate of gelatin after being inoculated with the cholera vibrio was further inoculated in two crossed lines with a microbe that was known to favor and another that hindered the growth of the germ of cholera. Cholera microbes grew luxuriantly along one line, but not at all along the other. The nearer the approach to the point at which the lines crossed the fewer the colonies of cholera germs. At the intersection, and for some distance around it, no colonies of cholera vibrios were to be found at all.

Metchnikoff succeeded in isolating from the stomach various microbes which favor the growth of cholera germs. In the first place a torula, which he found in the stomach of a hypopeptic individual, then a sarcina isolated from the stomach of another person, and finally a form of bacterium that does not liquefy gelatin. Microbes with the opposite power, *i.e.*, able to prevent the development of the cholera vibrio and even destroy it, have been isolated from the intestine. But not only does there exist a vital antagonism and a symbiosis among microbes, but there is also a chemical antagonism not difficult to demonstrate. This will cause a nutritive medium to especially favor the growth of a micro-organism at one time and absolutely prevent it at another. A culture medium that has sustained the growth of one set of microbes will present conditions favorable or unfavorable for the growth of succeeding microbes quite different from those which it originally possessed before any microbic life had been nourished in it.

If the staphylococcus aureus is allowed to develop on slanted gelatin for three days in a brood chamber it will at first liquefy the gelatin, then it will sterilize the medium by its own products and the gelatin will solidify as before. If tubes so prepared are now inoculated anew with the colon bacillus, the proteus vulgaris, and the bacillus icteroides, it will be found that the last does not develop at all, the colon bacillus does develop, while the proteus vulgaris develops with great luxuriance. On the other hand, where proteus has grown the staphylococcus aureus scarcely grows at all, the colon bacillus presents only traces of development, and the bacillus icteroides absolutely refuses to grow. Where the bacillus icteroides has lived all the other types of micro-organisms mentioned grow very well, most abundantly of all the proteus vulgaris.[6]

Because of the difficulty of placing a microbe that is being experimented with in conditions that will favor its growth, inoculation through the digestive tract has always given inconstant results. The vital and chemical antagonism of microbes always make it a most difficult problem, except where the experiments have been conducted in association with other means that favor the object desired by the bacteriologist.

Let us examine a few of the microbes which, either because of their immediate pathological effects or because of their being able to resist the action of the gastric juice, are able to gain a foothold in the gastro intestinal tract. The cholera vibrio is able to traverse the acid stomach and also to preserve its vitality for a longer or shorter period in the intestines without producing cholera. Animals that are very susceptible to cholera when the germ of the disease is injected intraperitoneally can absorb large amounts of the same culture by the digestive tract with absolute impunity. Metchnikoff could not produce cholera in rabbits except by taking the very young suckling animal and inoculating it at the

same time with certain microbes that favor the development of the cholera germ. Once the little rabbit had begun to live on ordinary forage, it was impossible to produce intestinal cholera in it, even with the aid of all the microbes that favor the growth of cholera vibrios that he had succeeded in finding. Rabbit mothers are well-known for their custom of eating their little ones when they see them moribund. From among a number of young rabbits in which Metchnikoff had produced intestinal cholera, three were eaten by their mothers after examination of them had disclosed their infection with cholera. The health of the mothers did not, however, suffer in the least.

To a young rabbit was administered a quantity of the contents of the cecum of a patient dead from cholera. This did not, however, contain any of the microbes that especially favor the growth of cholera. The animal did not take cholera, though it is needless to say that the intestinal material given to it to eat was swarming with cholera vibrios, so that Metchnikoff concluded that even the young suckling rabbits take cholera by the gastro-intestinal tract only when the germ of the disease is associated with certain microbes favorable to its growth.[7]

Strauss had heard that the veterinarians attributed "morve" in horses to contagion through the food. He cultivated the bacillus, demonstrated its virulence when injected intraperitoneally into guinea-pigs, but though he inoculated a large number of them he was not able to produce the disease by way of the mouth.[8]

It is well known that pest is eminently virulent when inoculated into mice and rats, yet when cultures of the bacillus or portions of the liver and spleen of animals dead of the disease are fed to them, while they often contract the disease that does not always happen. Mice that have often resisted food contaminated with pest bacilli, succumb at once to subcutaneous inoculations of the germs. Even these experiments of successfully inoculating animals with pest by the digestive tract, must be done with material that comes direct from cases of the disease in human beings or at least must not have undergone passage through more than two or three animals.[9]

It is so well known that it scarcely seems necessary to recall the fact that the bacillus tuberculosis can find a nidus for growth in all the organs and tissues, and that there is no animal known thus far to be refractory to the disease. In the laboratory it is ordinarily the guinea-pig and the rabbit that are selected for experimental work in tuberculosis because of their susceptibility to the disease, yet Harris and Gunther, by feeding rabbits with tuberculous flesh, succeeded in producing tuberculosis in but 2 out of 4 animals experimented with. Gerlach fed 35 animals altogether with tuberculous meat, yet only 8 were attacked by the disease. Johne fed 46 animals of different species with tuberculous material, but was able to demonstrate tuberculous lesions in only thirteen per cent. of the animals at autopsy. Nocard fed eleven cats with tuberculous flesh, but was able to find no lesions of the disease after the death of the animals. Peuch found that he had to feed at least 5 kilograms (11 pounds) of tuberculous flesh to little pigs if he wished to be reasonably sure of their having a general tuberculosis at the end of three months. All of these authorities are cited by Arloing, and scarcely tend to prove that it is easy to convey a contagion by the mouth.[10]

The animal that is most susceptible to the bacillus icteroides is the rabbit, which succumbs to the minutest intravenous injection of a culture of the bacillus within forty-eight hours at the longest, and dies infallibly from a subcutaneous injection in from four to five days. Notwithstanding this extreme susceptibility to the bacillus icteroides, I have myself on a number of occasions fed rabbits large quantities of warm cultures of the bacillus without being able to kill them, or even without being able to make them sick. I used three tubes of 10 c.c. of culture each, enough material to kill a great many of the animals if given subcutaneously. I suppose that it is because of this inconstancy of results in giving cultures by the mouth that Sanarelli does not even make mention of this form of experimentation. As for my own experiments with this method, I scarcely preserved the record of them for myself, and certainly did not think that an opportunity would come for publishing them.

It must be borne in mind, however, that Drs. Reed and Carroll, having fed little pigs with the bacillus icteroides, noted in two of them after death the characteristic lesions produced by the bacillus of hog cholera. What explanation can be given for this fact, especially when we consider it in the light of the exactly opposite results obtained by the same method by Drs. Wasdin and Geddings? The bacillus of hog cholera is a saprophyte so constantly present in the digestive tract of the hog that Smith[11] found it in the saliva of the animal, and inoculated with it without producing any pathogenic effect. Salmon, its discoverer, admits that there are a number of varieties of the bacillus, some more saprophytic than others. Loeffler, Cornil, Chantemesse, and Silberschmidt, while they admit that it can give rise to formidable epidemics, have found

it also in isolated cases.[12] Moore places it in the group of the colon bacillus,[13] and Smith advances the opinion that any other affection which weakens the organism of the hog and lowers its resistive vitality may permit the microbe to penetrate into the tissues and set up the disease, and with it an epidemic. Though it may seem far-fetched to admit this power of penetration on the part of the microbe, the fact remains that any debilitating cause may set up symptoms of the disease in certain neighborhoods, and the lesions of hog cholera be found at the autopsy.

I have not been able to study the symbiotic relations that exist between the bacillus icteroides and the bacillus of hog cholera. Knowing as I do, however, the intimate relationship which exists between the bacillus choleræ suis and the colon bacillus I think it would not be difficult to foresee what would happen when the bacillus choleræ suis and the bacillus icteroides were set growing side by side, for the bacillus icteroides, it is well known, favors the growth of the colon bacillus, and might be expected to do the same for the bacillus of hog cholera. A non-virulent colony of hog-cholera bacilli might, under the influence of the symbiosis existent between it and the bacillus icteroides, become malignant and productive of pathological lesions where it was but a harmless parasite before.

Vincent has shown[14] that the most innocuous saprophyte can become very virulent under certain conditions. He took, for instance, the bacillus megaterium and the bacillus mesentericus vulgatus (a form of potato bacillus), and changed them from harmless to extremely active pathogenic bacteria. When inoculated into animals in their primitive condition they produced nothing but a trifling and very temporary rise of temperature. When Roux's method of cultivation was applied to them, which consists in growing them enclosed in a small collodion sac enclosed in the peritoneum of animals, they soon became virulent. When grown this way, as the phagocytes have no chance to get at them in order to neutralize their virulence, they take on pathogenic properties, which gradually become intensified. After this continuous growth for some time in collodion-sac cultures, 4 drops of a culture of the bacillus megaterium killed mice in from ten to twenty hours, killed a guinea-pig weighing 450 grams in twenty-four hours when injected intraperitoneally, and in from two to four days when injected subcutaneously, while a rabbit weighing 1850 grams was killed in twelve hours by an endovenous injection. Vincent showed also that this microbe was modified by the presence of other micro-organisms, and grew much more luxuriously in the presence of a sterilized culture of the bacillus pyocyaneus or of the bacillus coli communis.

Under the circumstances the conclusion of Drs. Reed and Carroll that the bacillus icteroides is a variety of the bacillus of hog cholera seems, to say the least, precipitate. Experimental inoculation of a microbe by way of the mouth is a most insecure method, and conclusions drawn from results thus reached require the most careful examination before they can be accepted. All of the factors that I have mentioned as liable to modify the course of inoculations through the digestive tract must be taken into account or the conclusions will be liable to serious error.

SOME SURGICAL ASPECTS OF SYPHILIS.

BY FRANK HARTLEY, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE NEW YORK HOSPITAL.

IN writing a paper on this subject I feel that I must confine myself to my own experience and limit it to a description of those organs involved by syphilis which have come under my observation, rather than to attempt a collective article upon all organs which have been described as involved, and in which the failure to recognize the disease has been made. On this account I limit myself to the manifestations of syphilis occurring in the muscles, sheaths and tendons, bursæ, bones, joints, lymphatic glands, and rectum. I do not include any of the parasyphilides as compared with the syphilides, *i. e.*, manifestations of disease occurring in syphilitics in which the syphilis is not absolutely and necessarily the cause, and in which mercury and iodid of potash do not show their curative effects as in syphilis proper. The syphiloma (granuloma, gumma) resembles in growth and existence a simple specific inflammation, yet it demands a special interest of the surgeon, in that he not infrequently has

[1] Read at a Stated Meeting of the New York Academy of Medicine, held March 16, 1899, in a discussion on syphilis.

mistaken it for other neoplasms, and has subjected his patient to operative interference not always devoid of danger. Some of our most eminent surgeons have removed ulcerated gummata or tubercular syphilides of the lip and tongue for carcinoma, syphilitic gummata and ulcerating syphilides of the lip for labial cancer, gummatous ulceration and infiltration of the rectum for carcinoma. This danger is an ever present one to the surgeon to whom these cases are referred as malignant tumors requiring removal, and who, failing to identify any intermediary manifestation between the primary infection and the present lesion, or because of a too confiding belief in the history of the patient, which may be in error owing to shame, forgetfulness, or ignorance, believes them malignant processes without further investigation.

The tongue, a muscular organ, is the favorite seat for the granuloma of syphilis, and when the process is a diffuse infiltration with involvement of the mucous membrane and ulceration but little difficulty may exist in properly ascribing the cause. When, however, a gumma is circumscribed and exists deeply within the muscles of the tongue over which as yet the mucous membrane is intact, there is no reliable objective symptom by which one is able to differentiate between some abscesses, sarcoma, fibroma, and primary tuberculosis and actinomycosis; and the mistake has been made and recorded in literature again and again. Again, the presence of a granuloma in the tongue originating from several confluent foci although characteristic, for syphilis has been mistaken for carcinoma, especially in those cases in which no intermediary symptoms have been present, an exact diagnosis is often rendered difficult since in the majority of lingual cancers chronic inflammatory conditions and ulcerations are precedent to the carcinosis. Syphilis, so frequent in the tongue, especially in the form of neglected and unhealed syphilides, is a frequent precursor of the presence of cancer, and in several instances (quoted by Von Langenbeck) the gumma and the cancer have apparently appeared at the same time. The diagnosis is again obscured by the fact that many epithelial growths which cannot be distinguished from epithelioma in their histologic appearance are apt to be added to neglected and unhealed syphilides or lupus, in which appropriate treatment and the local removal of the epithelial growths are curative.

The lesions involving the muscles generally occur in the late varieties of syphilis, and either appear as a circumscribed mass or as a diffuse connective-tissue induration with or without disseminated gummatous foci, varying in consistency according to the relative amount of cellular constituents and interstitial inflammation. Its growth, whether slow and painless or rapid and painful, is attended by a more or less constant contracture of the muscle. It is situated usually at the juncture of the muscle and tendon, and varies in size from that of a walnut to a fist. The syphiloma selects most frequently the sternomastoid, and less frequently the masseter, cervicalis, tibialis posticus, the peronei, the triceps and biceps-brachii, biceps femoris, the infraspinatus, antibrachius, the pectoralis major, vastus internus, and the adductors of the thigh. Though these muscular lesions generally occur in several foci or in several muscles in some cases of the acquired variety after thirty to forty years, and in the hereditary and late hereditary syphilis, a single circumscribed lesion is the only manifestation, and a difficulty in diagnosis is at once presented. Though such a single circumscribed lesion is rare, it represents, according to Esmarch's experience, one-half of all the so called tumors of muscles.

Syphiloma in muscle has a great surgical interest since it attains good size and may easily be mistaken for a tumor. Langenbeck saw two inches above the clavicular attachment of the sternocleidomastoid muscle a gumma the size of a pigeon's egg. There were present in addition a pustular eruption and a gummatous orchitis. Had it not been for the constitutional symptoms present Langenbeck says himself it would have been difficult to differentiate from a fibrosarcoma. Virchow also saw a gumma the size of a fist in the trapezius muscle. Ricord recorded one in the tibialis posticus muscle the size of a pigeon's egg. Prescott Hewitt noticed in the adductor muscles of the thigh of a man thirty-five years of age a deeply seated, lobulated, and distinctly marked tumor. It had grown from a small nodule, and recently had grown more rapidly. All syphilis was denied. Inguinal lymphomata began to appear. Suspicion was at once aroused as to the character of the disease. The tumor disappeared under the use of the iodids. Senftleben saw a large gumma of the infraspinatus (six to eight inches) appearing as a sarcoma of the scapula. Although the patient had had chancre eight years before it was extirpated and the neck of the scapula sawn off. Microscopic examination showed it to be granulation tissue involving the whole muscle so that its nature was plain. Similar to this case is that of Langenbeck, in which a large gummatous tumor of the scapula was confounded for a time with a lipoma in a patient who denied syphilis and in whom Langenbeck found a gummatous testicle and post-chancral scar. Langenbeck also found in a thirty-six-year-old man, in the biceps brachii (lower one-third), a gumma the size of a walnut, which was

rapidly growing, painful, and not adherent to the skin. Infection was denied. Before an operation for sarcoma potassium iodid treatment was instituted. The tumor disappeared. Esmarch saw a healthy man of fifty, who for eight months suffered from pain in the tongue following talking and eating. Six months previously he noticed a nodule in the tongue on the left side. The rest of the tongue was healthy. Infection thirty years before with no subsequent manifestation. Cured with mercury and potassium iodid.

Of the infectious processes in muscle tuberculosis without other real marked manifestations is rare. As a primary process in muscle it is rarer than syphilis. As a secondary process and confined to the abdominal muscles and the tongue it is quite as frequently seen.

Tuberculosis in the tongue and elsewhere occurs either as a lupus, a miliary tuberculosis, a gumma, or an ulcer. The gummata occur principally in men. They either follow a primary organ involvement elsewhere or appear as a primary involvement. They exist beneath the mucous membrane and may remain three weeks to three years before softening in the center and forming an ulcer. No severe pain is present until ulceration takes place. Bacilli are seldom found in the discharge. Fourteen cases of this nodular form are described by Volkman, in five of which the disease was primary and in the rest it accompanied a phthisis pulmonum. The infection in these primary cases seems to come from the blood or lymph vessels and not from the sputum as in lingual ulcers. Cold abscesses, made up of confluent tubercular foci with glandular enlargement and phthisis pulmonum, have been reported sixteen times as occurring in the tongue.

The two varieties of tuberculosis of muscle—the gumma and the abscess—demand a diagnosis in the first place between tuberculoma, syphiloma, sarcoma, and a benign solid tumor. In the second place we must differentiate between a tubercular abscess, a congenital cyst, or an echinococcus cyst.

Actinomycosis and farcy scarcely concern us here as the involvement of the muscle in the first is secondary to that of bone, intestine, or lung, and in the latter, the distinctive and rapid course of the disease before muscular involvement as well as the manner of involvement allow an easy distinction. Moreover, here as in tuberculosis a bacteriological examination is decisive.

Tumors of muscle are at the best rare. Of these, the lipoma, the enchondroma, the osteoma, the fibroma, and cavernous angioma have been seen. Of these tumors of muscle the angiomata, situated in or beneath the deep muscles of the neck (their predilection place), present the greatest difficulty since their slow growth, their want of pulsation, their unalterability in volume during respiration render them very like lipomata, cold abscesses, lymphomata, or syphilomata. The lipomata of the tongue have been reported to the number of eighty, and their location has been almost invariably at the tip of the organ. The location, the softness, the yellow color, and the mobility of the mucous membrane over the tumor renders the differentiation from cysts and benign processes an easy matter. Congenital cysts and echinococcus cysts of the tongue are such great rarities and bear so few points of resemblance to the other tumors mentioned as to be left out of account. The sarcomata of muscle, however, are much more common and have been reported to the number of thirty-five. Undoubtedly many of the old statistics include a large number of gummata reported as sarcomata since fully one-half of all gummata seen by or sent to Esmarch as such were sarcomata and were cured by mercury and potassium iodid.

In the smaller cerebral arteries a circumscribed or diffuse obliterating endarteritis is not uncommon in the acquired variety. In the hereditary variety as a small solid infiltration of the adventitia of the vessels it is not infrequently seen in the bones and the viscera. Such a process is frequently seen in the larger arteries and usually leads to an obliteration of the lumen of the vessels. This process involving the arteries of the extremities may lead to gangrene and thus acquire surgical interest. In other cases where this process exists in the larger arteries it results in the development of aneurism or of a circumscribed or diffuse gummatous infiltration about the vessel.

In the former case where an aneurism is present, unless it be completely obliterated the differentiation will depend upon its multiplicity, its occurrence in early life, and the fact that sixty-nine out of every hundred subjects have syphilis as a cause. In the cases in which the process consists in a diffuse or circumscribed infiltration about the vessels, and in the exception to the former class, the mistake most frequently made has been to consider it a fibroma, fibrosarcoma, or neuroma. In the veins circumscribed gummata are not seen, though diffuse processes are known in a few instances. In all cases, the process has been an obliterating one, and the veins most frequently involved have been the portal, the femoral, and the internal jugular. The fact that this infiltration about the vessel has appeared years after infection and has, moreover, formed about the vessel a distinctly circumscribed

mass has resulted in attempts at removal of the process for a tumor.

Two cases have been reported by Greenhow as involving the femoral vein. One has been reported by Schüppel in the portal vein and Langenbeck has reported two cases, one in the common jugular vein, and one in the femoral vein. In both of Langenbeck's cases it was very observable that the infiltration formed a distinct mass about the vein, and in neither involved the accompanying artery but pushed it aside. In both cases the granuloma seemed to begin in the external and adventitial coat, although the internal coat was soft, friable, and had attached to it a completely decolorized thrombus, almost occluding the lumen of the vein. The first was one of a female of fifty-six years of age, the mother of eleven children, six of whom died of constitutional syphilis, and five of whom were living. There had been no evidence of syphilis for fourteen years. There was present a fusiform mass surrounding the common jugular vein. Extirpation of a mass including the vein for an extent of six centimeters. Diagnosis: sarcoma. Three years later gummata appeared upon the tongue and cheek which were cured with mercury and potassium iodid. Another case was in a female, forty-two years of age, who four years after infection, with very few intermediary symptoms, principally exanthemata, observed a mass growing slowly in the inguinal region. The mass was a fusiform one, involving and apparently surrounding the femoral vein. Although the diagnosis was made the mass including the vein was removed. A microscopical examination showed the tissue to be pure granuloma with many small cells showing a greater tendency to disintegration (fatty degeneration and detritus). The difficulty and the ease with which a diagnosis can be made is clearly exemplified in these two cases of Langenbeck.

The lymphomata occur as unusual lesions both in the acquired and in the hereditary variety. Clinically these glands may be either hard (sclerosis), or soft (gummatous). Though confined generally to a few chains of glands in the acquired variety they may, if hereditary, involve the mesenteric, lumbar, iliac, inguinal, thoracic, and cervical chains. Hence in some cases both in the hereditary and in the acquired varieties a differential diagnosis must be made between the lymphomata of syphilis and those of tuberculosis, of pseudoleucemia, of lymphosarcomatosis and those of carcinoma. Such cases have been repeatedly recorded by Esmarch, Verneuil, Ricord and Hutchinson, and their recitals are well known in literature. In 1880 Cunningham of Glasgow reported an interesting case of a man, aged thirty-five, who six years before had been infected. Four years after the infection and without intermediary symptoms the glands of the right side of the neck, thorax, and axilla became swollen, while those upon the left side were only slightly involved. The inguinal glands upon the right side were also much involved. The tumor in the neck measured 14 x 12 inches and was made up of soft, though normally shaped and enlarged glands. The condition at this time was thought to be either a pseudoleucemic lymphadenomata (Hodgkin's disease) or syphilitic lymphomata. Mercury and the iodid of potash was administered and within one month the tumor had gradually disappeared and the remaining glands were smaller.

Wunderlich had an exactly similar case and it is very probable that the cases reported by Billroth and Czerny as cured with arsenic were syphilitic lymphomata.

Two such cases have been observed by the author. The first case concerned a woman thirty-two years of age with acquired syphilis of seven-year's standing. Three years from the time of her primary lesion gummata of the lip appeared which were recognized and treated with inunctions of mercury and iodid of potash. Two years later lymphomata of the neck involving the submaxillary and deep carotid glands of the left side and the axillary glands upon the right side appeared. The cubital and occipital glands were only slightly enlarged. Some of these glands were soft and gummatous to the touch. Some were broken down and partly ulcerated, while others felt hard and stony. Under inunctions of mercury and the iodid of potash they disappeared, excepting those in the submaxillary region, which seemed hard and sclerotic. They were excised and under microscopic examination were found to be in a condition of sclerosis and calcification.

In another case, a man of twenty eight years, with acquired syphilis of six-years' standing with intermediary symptoms (exanthemata and skin gummata) presented lymphomata of the deep carotid and submaxillary chains upon both sides of the body. These glands were soft, rapidly growing and had been present for a period of two months. Under iodid of potash and mercury these tumors diminished in two months so as to be scarcely observable. Within six months the glands had entirely disappeared. He neglected treatment, however, and within a year returned with an enlargement of the same glands without ulceration, which under treatment again disappeared within a period of two months. Such a case, had the history not been known, would have given one the impression of a malignant lymphoma (pseudoleucemic lymphomata) since the examination of the blood showed nothing more than a

leucocytosis and no tubercle bacilli. Molliere, Casati, and others have called attention to this class of diseased glands in syphilis. Doyen himself has reported eight cases of hereditary syphilis in which four were attended with lymphomata involving more than a single chain of glands. In no case was there any breaking down of tissue except where the integument over them was involved. Occasionally these glands become enlarged, soften, break down and leave an ulcer with a hard, indurated edge and a gummatous and adherent base. Such glands may be mistaken for tuberculosis, but the ulcer in these is distinctive as its edge and base shows, or when healed it has an enlarged, adherent cicatrix with its areola of pigment. The deeper glands habitually suffer in hereditary syphilis; such glands as the lumbar, iliac, femoral, and mesenteric. They never suppurate. They occur in the form of an intestinal adenitis by which the glandular cells atrophy and the connective tissue increasingly contracts, or by a proliferation of these cells a soft, and more rounded shape is given them.

It is owing to these two conditions within the gland, when the process is not limited to a single chain of glands that the disease will so closely resemble lymphadenomata or lymphosarcomatosis. Treatment with iodid of potash and mercury as well as a histologic and bacteriologic examination will be required to decide the character of the case. In pseudoleucemic lymphadenomata as well as in the lymphosarcomata, the want of syphilitic manifestations and the anemia present, together with softness and rapid growth of the glands without ulceration, will generally suggest a diagnosis.

Leucemic lymphomata, however, and the enlarged spleen and lymphatic glands of hereditary syphilis may be easily confounded unless an examination of the glands and of the blood prove the case to be one or the other. The only reliable differential diagnostic point is the blood examination. In the lymphosarcomatosis no difficulty exists in a differential diagnosis so different is the course of the two diseases. In the tubercular lymphomata the course as compared with syphilis is slow and painless The ulceration occurs slowly and gradually and the distinction may thus be easily made from the development of the gland and the character of the ulceration; but as some cases of tuberculosis resemble so distinctly pseudolymphadenoma that they can only be distinguished by the examination of the blood; so they must be also distinguished from some of the syphilitic lymphomata. This also requires a blood examination.

The chronic hyperplastic lymphomata, which are rare, as well as the lymphomata following carcinoma, in which the primary carcinoma is not seen or observed, are the most difficult of all the cases to differentiate from the chronic sclerotic lymphomata of syphilis.

As a part of the lymphatic system I include here the tonsil. The tonsil as the seat of the primary lesion is not rare. Less frequent, but of more importance, however, are the ulcerations existing in the tonsil, the result of gummata either in the acquired or hereditary variety. In these cases it often becomes a most important question to distinguish between a true neoplasm and the syphiloma.

Of the new formations within the tonsil, syphilomata and lymphadenomata are by no means rare, and are by many considered to be more frequently found than lymphosarcoma and epithelioma. It has been my good fortune to see such a case with the late Dr. Jarvis of this city. A man, thirty-five years of age, having acquired syphilis fifteen years previously, and having no observable secondary lesion, presented himself to Dr. Jarvis for treatment of a quinsy sore throat. The tumor existed upon the right tonsil, was hard and indurated in spots, and soft in others. It was not ulcerated. It had persisted for a period of two months. The glands in the neck (submaxillary and deep carotids) were slightly enlarged. His treatment previously had been puncture, with partial excision and astringents. As no benefit occurred and the ulcer did not heal he presented himself to Dr. Jarvis for treatment. The ulceration present was one with fungous granulations. It had at its base a grayish discharge. The tonsil itself was enlarged, indurated, hard, and nodular. A consultation was had in which two of our best surgeons were present and recommended an immediate removal of the growth, their diagnosis being sarcoma. Owing to the danger and fear of the operation the patient for the first time admitted the history of his previous infection and some unmistakable lesions. Mercury and iodid of potash were immediately administered, and his disease was cured within two and one-half months.

The Breast.—The early manifestations of syphilis of the skin over the breast are not infrequently seen. The gummata existing within the breast, however, have only lately been conspicuously brought forward. Hennig, Abrosoli and Sauvages, Maisonneuve, Verneuil and Chever mention in all eight cases, but without particulars of the exact condition, although distinctly syphilitic and acquired.

Steng gives an account of a tertiary syphilide of the breast removed for cancer in a woman fifty years of age. The infection occurred twenty-eight years before. She was continuously treated with iodid of potash, but four years before her breast was

amputated for cancer. In the scar there appeared subsequently two hard almond-sized gummata. In six days they disappeared under treatment with iodid of potash. The proper inference to draw in this case is that the disease in the breast was a syphilitic gumma and not a cancer, as it is characteristic of syphilis to return in the character of a syphilide.

To Lancereaux and Langenbeck belong, however, the credit of accurately describing the involvement of this organ in its two distinct forms. (1) The simple syphilitic mastitis. (2) The gummatous syphilitic mastitis. Lancereaux describes three cases. The first variety is seen in both sexes. The gland itself becomes swollen and tense. The skin over it is not involved. The disease is apparently an interstitial process which in this stage presents nothing more than the feeling of enlargement and tenseness. It occurs in the second stage of syphilis, and may undergo under treatment a complete resolution. This process, when it becomes chronic and is attended by the formation of new connective tissue, may subsequently undergo contraction and give the appearance of what was formerly described under the name of deforming chronic mastitis without suppuration (Billroth).

The second variety exists as a hard lump, varying from the size of a pigeon's egg to a goose egg, within the breast. It produces little or no pain, and may continue for a long time without softening or may break down and form an ulcer which is characteristically syphilitic, that is, a hard, indurated border with fungous granulation tissue, on the surface of which there are gray adherent sloughs. This variety of mastitis may occur as a single lesion of an old syphilis or may be co-existent with other lesions of syphilis. Richet found such a case without any other manifestations of syphilis than the primary infection and cured it easily with the iodid of potash. Steers saw one without the manifestations of syphilis and operated upon it for cancer. An examination microscopically revealed the syphiloma. This disease though rare may be confounded quite naturally with tuberculosis which is also a rare disease here.

There are at present about forty-seven observations of this character. In twenty-three the tubercle bacilli were found. In twenty-four the histology was alone the diagnostic point, and of these twelve cases were primary and without other manifestations of tuberculosis; the rest were co-existent with other tubercular manifestations. The course of the process was painless, and the disease was only accidentally discovered. In one-half of all the cases the axillary glands were enlarged in the earlier stages. So long as a swelling alone in the breast is felt a distinction between syphiloma and a new growth is difficult. The probability arises when softening occurs and a cold abscess is present. The chronic course, the softening and the absence of other manifestations are the best signs for diagnosis, but these are not entirely positive as was shown in the case of Habermass. A woman forty-seven years old, the mother of fifteen children, had suffered from a painful, hard, indurated mass in the left breast for one year. It had gradually enlarged to the size of a hen's egg. The skin over it was not involved. The axillary glands were enlarged. An incision made into the mass evacuated a cheesy looking pus. The wall of this mass was indurated, not distinctly circumscribed, but losing itself in the neighboring portion of the process. Although macroscopically this appeared to be tuberculous, a microscopic examination of the wall of the cyst showed it to be a mammary carcinoma with abscess formation in the center, that is, an endocystic carcinoma mistaken for tuberculosis on account of its contents and its cystic formation.

Two cases which have come under my observation represent these two diseases very well:

Case I.— A female, aged thirty seven years. Syphilis at twenty-five. Nine years after the primary infection she presented herself with a nodule situated on the right side and in the upper and outer quadrant of the breast the size of a hen's egg. She had noticed it for about three weeks. It was painless. The axillary glands were slightly enlarged; the post occipital and cubital could be felt. It was a mass of an even consistency and was not broken down. The skin over it was absolutely uninvolved and the mass was circumcribed within the breast. In the previous history of the case the administration of iodid of potash had been followed with success. It would have been very easy, not knowing the history and not having examined the woman more carefully than is usually done, to have considered it a carcinoma and to have recommended an operation. As it was she was cured without operative interference.

Case II.—A female, aged twenty years, entered the Roosevelt Hospital complaining of a tumor in the right breast which was painless and had been noticed only a week previous to that date. The skin over the mass was uninvolved. The growth was about the size of a pigeon's egg. It was situated completely within the breast and the breast seemed to be infiltrated about the mass. It was adherent and distinctly circumscribed. The axillary glands on the right side were enlarged and on close inspection the center of the induration within the breast seemed to fluctuate; otherwise the mass was healthy. The diagnosis was made of probable tuberculosis. Operation was recommended and the breast and axillary glands were removed. A microscopic examination subsequently showed the tuber-

cle bacilli to be present. Recovery took place, and one year later the patient again presented herself with a similar process in the opposite breast. This was of the same character, and the same treatment was repeated. Two years later she was again seen. She was then the mother of two children, and was suffering from phthisis pulmonum, with bacilli in the sputum. Such a case as this on first inspection might have easily been mistaken for syphilis as the organs within the body at that time were uninvolved, and the disease in the breast was a primary lesion. On the second examination, however, the tubercular involvement of the lung was determined so that the disease would have been comparatively easy to diagnose.

Actinomycosis does not attack the breast except as secondary to the bone or the thoracic organs. As a primary disease in the breast it has not been observed. A primary actinomycosis of the skin, however, has been observed. It resembles tuberculosis and syphilis in that it consists of a circumscribed indurated area which breaks down and leaves a granuloma, and as it advances from the periphery in all directions it may invade the breast secondarily and render an immediate diagnosis doubtful until the actinomycoses are found. The sclerosing or interstitial mastitis may simulate in its progress scirrhous carcinoma, and the circumscribed gumma within the breast may be difficult to diagnosticate. The tuberculoma is of the first importance, and next in order come the fibroma, the adenoma, the cystadenoma, the cystocarcinoma, the sarcoma and the cysts. All chronic inflammatory processes gradually disappear or soften and form abscesses When such nodules remain for a month or a year unchanged, and possibly are slightly nodular and often only painful during menstruation, they are generally innocent fibromata. If they grow slowly or continuously they probably represent adenomata, cystadenomata or echinococcus cysts, and if their growth is still more rapid, a sarcoma, cystosarcoma, or an endocystic carcinoma.

(To Be Continued.)

BOTTINI'S OPERATION AND OTHER TREATMENT OF THE ENLARGED PROSTATE.[1]

By ROBERT NEWMAN, M.D.,
OF NEW YORK

PROSTATITIS may appear any time in life but occurs generally in young men or in those of middle age. It is an inflammation which has progressed from an acute to a chronic stage. It may result from sexual excesses and sexual perversion, particularly masturbation, unskilful use of the catheter, violence, the use of caustics, or of strong injections in the deep urethra, and as a result of gonorrhea. The principal symptom is soreness or severe pain, spreading in all directions. This pain is of a dull, aching character which is aggravated by the touch of any instrument inserted for the purpose of investigation or treatment. It is referred to the perineum, rectum, urethra, and bladder, even to the suprapubic region and the pelvis. Urination causes scalding, and coitus and ejaculation is so painful that intercourse is made almost impossible. Epithelium appears in the urine as flocculi or thin shreds. Hyperemia of the parts can be seen on endoscopic examination, which often causes bleeding. Complications occur in adjacent parts, and manifestations of a general neurasthenia may ensue.

The treatment should first be directed toward allaying pain and irritation before radical measures for cure can be commenced. Irrigations of hot water, simple or medicated, are very important. It is best to use a syphon arrangement with a nozzle not longer than one or two inches. The water receptacle should be placed sufficiently high so that the fluid will be propelled by gravity, and thus no instrument will be in contact with or irritate the hyperemic portion. Anodyne suppositories should be employed and ointment of a similar kind should be injected into the urethra. Benzoinol with cocain deserves particular mention. When the painful irritation has subsided the writer has often effected a cure by local galvanization. The electrode must be introduced with great gentleness and must not be pushed onward while the contact with the prostate gland gives rise to pain. The galvanic current must be mild, from 3 to 5 milliamperes. The electrode in the urethra should be connected with the negative pole while the positive-pad electrode is held by the patient. Sometimes it may be well to begin with high-tension currents as an analgesic. The writer objects to the local application of nitrate of silver, which generally over-stimulates the parts and thereby makes matters worse. Any treatment requires time, care, and patience on the part of the surgeon and the patient, but if such is exercised the result will be a cure. Hygienic measures and rest must be insisted upon. Surgical interference has been recommended, and prostatectomy in various ways performed, the consideration of which must be omitted here on account of limited time.

Hypertrophy of the prostate differs from prostatitis in that it is a disease of advanced age and is not painful. The prostate is scarcely sensitive to the touch. The enlargement acts as a mechanical obstruction to the bladder which prevents a free flow of urine. Cystitis develops with dilatation of the muscular walls, frequent micturition, and often retention. Other sequels of the obstruction to the

[1] Read at a meeting of the Northwestern Medical and Surgical Society of New York, June 21, 1899. For discussion, see page 413.

passage of urine are ureteritis with dilatation of the ureters, pyelitis, and pyelonephritis.

The treatment of prostatic hypertrophy has changed from one extreme to the other. In former years the patient was condemned to use the catheter for a lifetime, which was a very indefinite period and it generally increased the trouble. At present the condition may be attacked surgically by way of the urethra, perineum, rectum, or suprapubically. Electricity has also been used in different ways.

It is more than twenty years since Bottini devised and practised the operation on the prostate with the galvanocautery. It consists in burning a passage through the enlarged gland by the galvanocautery, thus enlarging the passage and removing the obstruction. The burner is made of heavy platinum encased in an instument resembling a lithotrite. The burner is heated red, or even hotter, by a storage battery, and by a screw slowly advanced through the obstruction. Antiseptic precautions are advisable, particularly of the bladder. It is still a mooted question whether the bladder should be filled with air or with water. A local anesthetic to the prostatic portion of the urethra is absolutely necessary, cocain being preferable. Some patients may choose ether narcosis. Several incisions forward and backward may be made if the operator finds such a procedure necessary. During the passage of the burner the operator may guide it by placing one finger in the rectum. The whole operation may be completed in a few minutes.

Attracted by the first reports of this operation the writer performed it several times. The late Dr. Guleke of New York had imported an original Bottini instrument with which he and the writer operated. These operations were performed in 1882 and 1883, but as they were not satisfactory to us the details were not specially reported, but my own objections were treated of in other papers. This fact explains the incorrect statements of recent reports in 1897 and 1898 to the effect that the Bottini operation had never been performed in this country.

Not having had the expected result from my experience with the Bottini instrument I constructed my own galvanocautery sound for the treatment of hypertrophied prostate, which was described in a paper read before the Surgical Section at the thirty-seventh annual meeting of the American Medical Association at St. Louis. The paper was published in the *Journal of the American Medical Association*, August 28, 1886. This instrument in a new garb and improved was again described in a paper, entitled "The Galvanocautery Sound and Its Application, Especially in Hypertrophied Prostate," read at Washington, before the International Medical Congress, September 8, 1887. It was published in the Transactions of the International Medical Congress as well as in the *New England Medical Monthly*, December, 1887. In these papers I described the Bottini method, expressed my full appreciation of it, and also stated the objections. If I had not performed Bottini's operation I would not have been able to criticize it, nor would I have devised my galvanocautery sound, which has worked very satisfactorily. While I admire the genius of Bottini I object to the following points from my personal experience in 1882:

1. The instrument was clumsy, unhandy and heavy.

2. The platinum burner was so thick that it got hot too slowly and when hot lost its shape by bending so that sometimes it would not move back into its beak.

3. The very large storage battery was too heavy for transportation and a smaller one did not generate enough heat.

4. The instrument was shaped like Heurteloup's lithotrite, the end having only a short condée. Such an instrument is exceedingly difficult to introduce, and in many cases of hypertrophy non-introducible, the mechanical obstruction leaving no space for its passage.

The intention is to push the instrument into the bladder over and beyond the enlargement of the prostate, then to reverse it so that the beak is turned downward. The galvanocautery knife is hidden inside the beak and moves outward when the dial is turned on the handle as the battery heats it, thereby making a central cut in the obstructing prostate.

5. The result of this operation was very uncertain. It sometimes caused shock, pain and inflammation and irritated the bladder, and the exfoliation of the scabs caused by the cautery gave rise to more complications. It may be again stated that the effect of the galvanocautery is really a burning through the tissues entirely different from electrolysis, which is a chemical absorption.

6. The patient has to remain in bed for weeks, and from some reports made by Bottini himself it has been shown that voluntary micturition occurred only after twenty-four days.

7. The operation is not free from danger.

For the above reasons I constructed my galvanocautery sound. The instrument is catheter-shaped, of smooth, polished metal with a short curve at one end. At this end is a fenestrum in which is placed the platinum wire, the burner to be heated. A serpentine form is best for this wire. Each end is firmly attached to one of the two copper rods inside the tube and represents respectively the positive and

negative pole. The other end of the instrument is straight and forms the handle, in which extend the copper rods, each of which is fastened to one of the pins or heat conductors. These two pins are connected with electric cords by binding screws. The other ends of the two electric cords are fastened respectively to the positive and negative pole of the battery. The current-breaker is movable, and when set straight and pressed firmly down on the screw electricity is evolved and the burner instantaneously heated. The improvements consist in (1) the handle being in one light, convenient piece; (2) having the current-breaker under the immediate control of the index finger; (3) having the fenestrum filled up, by which means the instrument is more thoroughly insulated and less liable to become heated; (4) having the tube filled up, thus preventing it from getting wet or blocked with debris. A storage battery is used to heat the wire.

The method of using my galvanocautery sound is as follows: It is connected with the storage battery and the potential regulated by means of a rheostat. That portion of the prostate to which the cautery is to be applied must have been ascertained and the distance from the meatus measured. The instrument is then introduced so that the fenestrum with its platinum wire is in contact with the part to be cauterized. One hand of the operator holds the instrument firmly in place while the other hand sets the battery in motion. The current-breaker is placed in a straight line and pressed firmly upon the screw, a flash follows, and the raising of the finger from the current-breaker disconnects the current. In one minute the operation is finished and the instrument withdrawn. In causes no pain, and in some instances the patient scarcely believes that anything has been done. He is able to walk about and is not detained from his business. In the case of very sensitive patients I have used cocain injections, but it was scarcely necessary. The séance should be repeated in about three days, or even in two. The instrument must be kept scrupulously clean, as the cautery will fail to work if there is dirt between the connections.

The question now arises, How does this method bring about a cure? The end sought is first to remove the obstruction so that the bladder can discharge all the urine, and at regular intervals, and then to reduce the prostate to its normal size. The theory is that the cautery first acts as a tonic and next as an astringent; the mucous lining shrivels up, and the glandular tissue contracts, and by shrinkage the size is diminished. The stimulation gives new life and healthy action. Each repetition of the operation acts similarly, and perhaps on another part of the hypertrophied gland. The operation must be repeated until a cure is effected. Care must be taken not to over-stimulate and thus cause prostatorrhea, prostatitis, etc., thereby aggravating the very ailment we seek to cure. The cauterization must be just severe enough to accomplish the object and no more. If it is too prolonged and too deep the glandular action is overtaxed and weakened and the operation will be followed by a terrible prostatorrhea which requires a long time for cure. At the same time an inflammation is created which causes pain and swelling, and the over cauterized tissue will slough and septicemia may ensue. For these reasons I prefer the slow method described and am opposed to rapid methods and to too deep cauterizations.

In the treatment of an enlarged prostate by the galvanocautery it is absolutely necessary to pay attention to other symptoms and troubles of the patient according to established principles. Pain must at all hazards be allayed. While the galvanocautery is used it is of the greatest importance to attend to the state of the bladder by drawing off the urine and washing the viscus out. This treatment is indicated in all cases of enlarged prostate in which urgent necessity for immediate relief does not exist, and particuiarly in cases in which the patient is walking about. It is useless if the patient is in the last stages of albuminuria, when uremic poisoning may carry him off at any moment. The earlier the treatment is instituted the better the results which may be expected.

A modification of Bottini's apparatus was made about two years ago by Freudenberg of Berlin. This device is a great improvement and does away with some of the objections experienced in former times. Freudenberg describes his modification as follows: "The modifications in point are relative to shape, handiness and electrotechnical construction, affording at the same time the possibility of sterilization. The modified instrument is provided with a stout cylindrical, grooved handle, strong and steady in the hand, quite resembling the well known handle of a lithotrite. The cooling apparatus is inserted on this side of the handle, instead of at its farther extremity, thereby obviating incandescence of the handle, and securing the rubber hose of the cooling apparatus from being compressed by the ulnar aspect of the hand. In lieu of the platinum blade platino-iridium is used, this alloy being harder and so less apt to bend, and by reason of its electrical resistance permitting of the employment of the weaker current for rendering the blade incandescent. Another addition consists in the conduction of the current ascending to the knife within the guide through a single wire only, equaling in volume the

two wires used in the original instrument; the descending current passing through the hull proper, and by reason of its close contact with the cannula, through the entire length of the external instrument. Moreover, greater steadiness of the blade, riveted as it is to the inflexible hull, is assured. The connection of the instrument with the conducting wires has been achieved by a process corresponding with the axis of the instrument and leaving both poles in a concentric arrangement. A slight jerk will move up the corresponding cable attachment to which the cables are fastened: these are united to one conducting wire, and owing to the improvements of electrical construction are much thinner than formerly.

"Interpolation and interruption of the current are effected by a minute screw, superseding the special interrupter of the original apparatus. The last alteration is the employment of a water-proof and heat-proof putty which, by tightening and isolating the apparatus, allows of its being treated *in toto* like any other surgical instrument, not only as to antiseptic solutions, but as to sterilization in boiling water, a process we could not formerly have applied without seriously damaging the instrument."

The operation as modified by Freudenberg has lately become a favorite one with the profession and within the last few months many reports have appeared. Some of the objections to Bottini's incisor have been removed by Freudenberg's modifications, some still remain, and it is desirable that the future will create an ideal instrument for the purpose. Freudenberg himself reports thirteen cases, with the following results: Relieved, 4; greatly improved, 3; benefited, 4; deaths, 2.

MEDICAL PROGRESS.

The Significance of Imperfect Vaccination Pustules.—CASTERET (*Presse Medicale*, June 24, 1899) has attempted to determine the significance of badly formed vaccination pustules. On the second or third day after vaccination a little pustule may form and undergo three different evolutions: (1) it may disappear on the fourth or fifth day—*unsuccessful vaccination*; (2) it may go on and develop by the seventh or ninth day into an umbilicated vesicle—*successful vaccination*; (3) or it may form a pustule surrounded by an area of inflammation which dries up on the fifth or sixth day—*doubtful vaccination*. The nature of pustules of this character has been much in dispute. Some have asserted that they were due to various germs and the name "false vaccination" has been given to the condition. Others, and among them the author, have maintained that they are manifestations of the vaccine material itself. If material from such a pustule is inoculated into a heifer it will produce the typical eruption of vaccinia. They represent an abortive type of vaccination, the material not having arrived at its complete development. They certainly render the individual immune since revaccination two or three months afterward does not take. Some of these doubtful vaccinations are due to a weakened vaccine as shown by the slow development when the material is inoculated into a heifer. After such an inoculation the material regains its normal power, and will act upon a second heifer as normal vaccinia material. After this second inoculation it will also produce good vaccination pustules in human beings.

Abdominoperineal Proctosigmoidectomy.—ELLIS (*Atlanta Jour.-Rec. of Med.*, August, 1899) suggests an operation for the removal of malignant disease of the rectum or lower portion of the sigmoid to which he gives the above title. It is a grave operation but it gives apparently the best chance of a radical extirpation of the diseased tissues. A suprapubic abdominal incision is made, and at the last lumbar vertebra the internal iliac arteries are located. At this point they are a little over an inch from the median line. The peritoneum overlying each artery is divided, care being taken to avoid the ureter which is thus drawn outward. The artery is separated from its vein and ligated. The sigmoid flexure is then dissected free after the ligation, if necessary, of the inferior mesenteric artery. The gut is tied above the tumor with gauze in two places, and divided between the ligatures after compression by a clamp. The cut ends are immediately wrapped in sterilized gauze to prevent soiling of the wound, and the liberation of the rectum is continued downward into the pelvis as far as is convenient. The gut which has thus been freed is dropped into the pelvis and packed above with sterilized compresses. The abdominal wound is closed and an artificial anus is made in the left iliac region. The patient is then placed in the lithotomy position; the anus is plugged and an elliptical incision made through the skin around it. The levators are divided and the anterior surface of the rectum is separated from the vesical triangle with especial care. The whole of the severed intestine with the overlying compresses is drawn out through the perineal wound. The cavity is packed with gauze and permitted to close from above downward. The writer does not claim especial originality for this method of operation in which he has attempted to combine the best points in the operations of Doyen, Gussenbauer, Hochenegg, Quenu, Allingham, and Von Bergmann.

Successful Out Door Treatment of Tuberculosis in London.—SOMMERVILLE (*Lancet*, July 22, 1899) gives the history of a cure of tuberculosis by out-door treatment in London which shows in a striking manner how success may follow the carrying out of the best therapeutic measures even under apparently adverse circumstances. The patient was a German, aged twenty-one years. The diagnosis of incipient phthisis rested upon physical signs and the demonstration of tubercle bacilli in the sputum. The appetite was poor and there was an evening rise of temperature of 1½ to 2 degrees. Circumstances pre-

vented his leaving London. He was put upon a daily diet which included five or six eggs, a bowl of oatmeal porridge with new milk, beef, mutton, chicken, ham, a little claret, and a very small amount of brandy in or after a large glass of milk night and morning. Cream, puddings, and various minor dishes were also allowed. Altogether he took from five to six pints of milk daily. The appetite at first was poor and the digestion not what it should be, but as time passed and the quantities of the above-mentioned foods were increased, both appetite and digestion improved. The greater part of each day was spent out of doors, walking, driving, etc., a rest being taken before lunch and dinner. The excursions were mostly contrived under the guide of a woman friend, so that they had some objective point of interest. The patient took a quinin mixture containing a little compound camphor and used an inhalation of carbolic acid and iodin. In seven weeks, bacteriological examination failed to show any tubercle bacilli in the sputum; the cough and sputum had almost disappeared; there was no further hemoptysis; the pulse had fallen from 110 to 80; the temperature was normal; the râles had disappeared from the apices, and the subclavicular and intraclavicular hollows were filling up, and the patient had gained fifteen pounds in weight. The writer attributes no small share of the success of the treatment to the clever way in which the patient's friend managed him. He was saved from the depressing effect of associating with others in a similar condition, and his out-door life was made more a matter of pleasure than a means of seeking health.

The Therapeutics of Painful Deglutition.—YONGE (*The Therapist*, July 15, 1899) made a series of observations with fourteen local anesthetics with the object of determining the most suitable substance in this class for palliation of laryngeal or pharyngeal dysphagia. Nine of them seem to possess considerable value under different circumstances. They are cocain, antipyrin, carbolic acid, guaiacol (with or without menthol), eucain, morphin (with or without iodoform), paramonochlorphenol, and orthoform. Nitrate of silver in solution, if used as a spray for laryngeal ulceration, produces a film which protects the denuded surface from further irritation. Cocain he found to be one of the best, but it has the disadvantages of transitory action, toxicity, expensiveness, a bitter taste, and the production of a constrictive feeling. Ice-cold solutions of cocain appeared to have at least double the anesthetic power of solutions of ordinary temperatures. A combination of cocain with antipyrin (five per cent. of the former to twenty per cent. of the latter), used as a spray gave relief in moderate degrees of pain for two or three hours. In perichondritis of the larynx a thirty-per-cent. solution of antipyrin was found superior to cocain in that the effects lasted much longer and the quantity of the drug required was in most instances innocuous. Eucain B. appeared to be preferable in children. He found a twenty per cent. solution of carbolic acid approximately equivalent to a one or two-per-cent. solution of cocain.

Dysphagia resulting from a tuberculous ulcer of the larynx may be quickly relieved by puncturing its floor with a specially curved syringe and injecting one minim of pure guaiacol. He mentions an instance of this character in which dysphagia was so great that rectal alimentation became necessary although the patient's appetite was ravenous. One week's treatment with guaiacol sprays and two injections of one minim of guaiacol in the floor of the ulcer caused the dysphagia to disappear and the ulcer soon healed. Insufflation of morphin and iodoform is an old method of treatment. A more recent application and one of great value in advanced cases of laryngitis in which any direct attempt at applying drugs causes distress, is prepared as follows:

℞	Morphiæ hydrochlorat. . . .	gr. ⅙
	Mucilag. acaciæ	ʒ j
	Glycerini	ʒ ij
	Aquæ . . . . q.s. ad	ʒ j.

This mixture is administered in sips before each meal. The sticky fluid clings to those parts which the food will touch on its way into the esophagus and thus temporarily relieves the pain of deglutition. The method is applicable for syphilitic and malignant ulceration.

Paramonochlorphenol has been highly recommended by Simanowsky and Spengler of St. Petersburg for tuberculous laryngitis as both palliative and curative. It is employed in solutions of from five to twenty per cent. in glycerin. These are rubbed into infiltrations and ulcerations with an ordinary curved cotton applicator. The administration causes acute pain, which is followed, however, by a prolonged anesthetic effect. Orthoform is a powerful anesthetic, not so potent as cocain, but more suitable for prolonged application by reason of its innocuousness. The anodyne gives relief in from five to ten minutes and the effect lasts from a few hours to four or five days, owing to the slow solubility of the substance. The drug has no effect upon unbroken mucous membrane. It is necessary that the nerve-endings be exposed. It is well known that fluid thickened with flour, arrowroot, etc., is less painful to swallow than either solids or liquids. Sucking small pieces of ice before a meal gives considerable relief. In ulcerative conditions of the larynx a patient can sometimes swallow with comfort if he lies flat on his stomach and sucks up nourishment through a tube from a cup placed on a chair by the bedside; or, while in the same position, food may be swallowed in gulps to avoid the choking and coughing which is due to imperfect closure of the upper part of the larynx. The use of the esophageal tube has been advised but it causes such discomfort that rectal feeding seems preferable. No single remedy exists which will relieve all forms of dysphagia, but when one anesthetic fails another may succeed, so that there need scarcely be a patient who is forced to turn away unrelieved.

Silver Catgut Sterilized by Dry Heat. — BOECKMANN (*St. Paul Med. Journ.*, July, 1899) predicts that the time will come when the preparation of catgut will be perfected to such a degree as to make it an ideal material for sutures and ligatures. It is proven beyond a doubt that aseptic catgut does not give rise to any trouble if it is not infected by the hands of the operator and is applied in aseptic localities. Therefore, in cases of failure the writer blames himself rather than the catgut. The ideal

gut must be pliable, durable, clean, sterile, and, last but not least, antiseptic. It is safe to assume that all catgut is contaminated with chemical and mechanical impurities. Clean catgut ought to look perfectly white but it is yellow if fat is present. Chemical solvents, such as alcohol, ether, turpentine, and benzine, dissolve more or less of the fat contained in the gut but this is rather a disadvantage as the gut is thereby rendered dry and less pliable than before, and one does not know to what extent they dissolve the toxins. The first process in cleansing the gut should be a scrubbing with soap and water. Catgut bundles which contain ten strands are spread out on an inclined washboard and kept in place at top and bottom by pegs. The bundles are scrubbed with a clean sponge and sterile hot water containing green soap, the hands having previously been scrubbed and the fingers covered with rubber tips. After fifteen minutes of scrubbing the bundles are rinsed in sterile water. The second step is to make the gut antiseptic. Sublimate coagulates albumen and does not seem to penetrate properly. Carbolic acid impregnates the gut but is disposed of much sooner than the gut itself, thus rendering the latter a culture medium for bacteria on which the carbolic acid exercises an inhibitory action while present. Iodoform decomposes into free iodin, making the gut brown, irritating, and brittle.

Credé impregnated catgut with a one-per-cent. solution of lactate of silver for one week and afterward exposed it to the bright sunlight for the purpose of reducing the silver salt under the supposition that the gut would be sterilized by the pure silver thus produced. Boeckmann repeated his experiments and found the silver catgut superior to any other antiseptic catgut, although he does not trust to the sterilization thus obtained. He decants the solution after one week and puts the jar which contains the strings in the sunlight with a piece of gauze over its mouth until the gut turns black. The jar is then filled with sterile water several times and shaken until the water remains perfectly clear. The strings are then uncoiled and stretched back to their natural size by weights in a case which protects them from dust but exposes them to the sunlight. When perfectly dry they are cut up into desirable lengths, rolled up in separate coils, placed in different hardening fluids, and again exposed to sunlight. The silver gut will last about five days in the tissues. If hardened in alcohol it will last about a week. If immersed in a one-per-cent. solution of formalin-alcohol it will last about two weeks in aseptic tissues. This ought to suffice for any purpose, but if any surgeon wishes a more durable material he can obtain it by hardening the gut in a five-per-cent. solution of formalin. Such gut will last about six weeks. The hardening solutions are decanted and the gut again dried by placing the jar in an incubator. The strings are wrapped in paraffin paper and placed in envelopes which are sealed. The envelopes are heated in a dry sterilizer at a temperature of 280° F. for three hours or more. This dry sterilization disposes of all handling of the gut until the moment when it shall be used. This method of preparation is more suited to the laboratory than to the surgeon's office, but the product is such a satisfactory one that Boeckmann looks to see catgut so treated supplant catgut prepared in other ways as well as kangaroo tendon.

THERAPEUTIC NOTES.

Non-Operative Treatment of Tuberculous Peritonitis.—Byford (*Va. Med. Semimonthly*, July 21, 1899) does not believe that the cure of tubercular peritonitis, which so often follows abdominal section, is due to the slight operative interference. Observation has taught him that tubercular peritonitis is increased and the patient is prevented from getting well by the intestinal irritation which is produced by the ingestion of improper food. If this source of irritation be avoided, the patient will usually recover without other medicinal treatment. During the first few days of an acute attack the patient should receive the treatment that is suitable for an acute peritonitis. After the first few days no opium should be allowed, but hot fomentations should be applied to relieve pain. Enough calomel should be given to turn the stools to a dark green, and afterward divided doses of salines sufficient to produce two or three soft stools should be administered each day. The diet should be fluid, in small quantities, so as to avoid the production of intestinal gases. Later such solids may be given as will neither produce gas in the stomach or bowels, nor leave a solid residuum. The patient should be kept in bed until all abdominal tenderness is gone and the evening temperature is almost normal. Later, when there is any rise in temperature or indication of abdominal tenderness, he should again remain quiet. Salol, guaiacol, and creosote are helpful in keeping down intestinal fermentation, while toxics, stimulants, and general antitubercular remedies should not be neglected. For several months the diet should be carefully regulated. It is Byford's belief that the rest in bed and scanty diet are responsible for the cures of tuberculous peritonitis which sometimes follow operations performed upon patients suffering with this disease.

Chronic Eczema Treated by Naftalan.—Rosenbaum (*The Therapist*, July 15, 1899) gives a résumé of his experiences with naftalan, especially in burns and acute chronic eczema. The results obtained in chronic eczema were far more striking than those obtained in acute eczema. One man had suffered for more than twenty years from an obstinate eczema of both hands, with tormenting itching. The skin was cracked and so covered with crusts that he always wore gloves in public. In a short time after the naftalan treatment was begun the itching ceased, and the skin rapidly took on a normal appearance. The application of naftalan once a week at night was sufficient to preserve this good condition of the skin. In another patient, a woman, there was an eczema which extended over almost the whole surface of the body, so that the appearance was similar to that of ichthyosis. In forty days after the commencement of the treatment with naftalan she was completely cured.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

THE CONDITIONS OF INFECTION.

THE paper we publish this week on "Infection through the Digestive Tract" by Dr. Felix Vitale, a former co-worker with Sanarelli, is of special interest not only as a contribution of importance to the discussion on the etiology of yellow fever, but as a suggestive review of some of the conditions of infection as the knowledge of them is gradually being evolved in the progress of modern bacteriology. Symbiosis and antagonism, the influence of microbes upon each other in a favorable or unfavorable sense, is the question that is occupying most attention just now. That germs, so-called, are not wholly evil in their influence has of course been known for a long time, but the realization that certain forms among them actually act as our protectors against others by inhibiting their growth has only come in very recent years.

With the knowledge of this fact it is easier to understand that pathogenic germs, such as the diplococcus of pneumonia may be almost constantly present in the saliva of even normal individuals, and yet not produce the disease, or that the diphtheria bacillus may lodge in a healthy throat for weeks or even months without doing harm. The antagonism of other flora of the mouth is of course not the only reason that prevents the outbreak of such diseases, but it is an important reason, and it emphasizes the necessity for the avoidance of any drastic measures that would disturb Nature's perfectly but very delicately balanced microbic equilibrium for protective purposes. This disturbance of bacterial equilibrium constitutes an important element in the greater prevalence of certain diseases during certain seasons of the year than at others, and gives the probable clue to the occurrence of various intestinal disturbances when the changing of drinking water, for instance, in removing from one place to another gives entry for the moment, at least, to an entirely new crop of intestinal flora between which and the former indigenes a new equilibrium of symbiosis or antagonism must needs be established. The question of infection is a much more complicated one than has been imagined. Intestinal antisepsis takes on a new appearance in the light of this bacteriologic advance for it may prove that so-called intestinal antiseptics disturb bacteria that otherwise do good rather than harm by their presence in the digestive tract. In general, the lesson *non nocere* comes out still more forcibly than before and makes clear the importance of conservative medication.

INJECTIONS IN INTUSSUSCEPTION.

IN *Pediatrics*, April 15th, Clubbe reports eight cases of intussusception treated by laparotomy with six recoveries. This is a very good showing, and it naturally follows that his advice to precede an operation with an oil injection demands serious consideration. This old method of treatment is not very highly esteemed by most surgeons of to-day. Their objections to it are of the general character, that it wastes valuable time, that it can do no good and may do harm, and so forth, though some writers advise its employment in the early hours of the obstruction.

Clubbe takes a positive stand that the injection of warm olive oil should be employed in every case, no matter at what stage the patient is seen. He says that he has reduced the obstruction in six patients by this means alone, and as he always makes the injection after the patient has been prepared for operation and the anesthetic has been given, very

little time is lost, and the decision to operate is in no way interfered with, unless, of course, the injection is successful in reducing the intussusception. The greatest advantage he claims for it, however, is, that in almost every case, the intussusception will be partially reduced, and that in the gentlest manner; and, by the more exact localization of the unreduced portion which follows, the abdominal incision can be made directly over the lesion. Hence the operative time may be shortened rather than lengthened by an injection given while the child is under the anesthetic.

COLLES' LAW AND ITS EXCEPTIONS.

Supposed discoverers in medicine have fared rather badly at the hands of the present generation. Nearly always some one has been able to point out, or thought he could, that the discoverer was anticipated by some one else of whom, as a rule, the world had heard practically nothing. Colles has suffered with the rest, and French syphilographers, notably Fournier and Morel Levalée, have pointed out that the first one to formulate the law so long known as Colles', that "the paternally syphilitic child will not infect its own mother," was really Baumés, a French physician, and that in all justice he should be given credit for it. It is not probable, however, after its long years of use that there will be any change in the designation of the law.

Of more interest is the fact that in recent years a certain number of exceptions to the law seem to have been pointed out. These have not been of sufficient number to absolutely impugn the truth of the law in general, but they seem to show that there are special cases that either escape from its influence entirely or in which the protection afforded by it is but transitory. The principle on which the law affords protection is still in dispute. While Fournier considers that the mother is protected because she has been actually infected with syphilis, though in a mild, or, as he calls it, Platonic form, Finger of Vienna and Von Düring of Constantinople think that she has only been rendered immune. This immunity they suppose to be due to the absorption of toxins and perhaps antitoxins from the fetal blood without actual infection by the micro-organism of syphilis. It can readily be understood that immunity thus produced might be of comparatively short duration. The observations of bacteriologists on other diseases have shown that the immunity secured by antitoxins is not lasting. The protection afforded by prophylactic injections of diphtheria serum lasts not more than three weeks. Some years ago the brothers Klemperer pointed out that the protective substances exist in the blood of pneumonia patients for even a shorter time than this. Whether we have in such considerations an explanation of the reason for certain reported exceptions to Colles' law remains to be seen.

A very striking case reported by Dr. Neuhaus of Munich in Unna's *Monatshefte für Praktische Dermatologie*, June 15, 1899, shows that the protection afforded the mother by having borne a syphilitic child did not protect her from infection from without, six months after the birth of her child at a time when the child had been dead for some months. In this case there could scarcely be question of reinfection after only six months of supposedly absolutely latent syphilis, and it is much more probable that the infection noted was primary. There evidently remains some careful collating of cases yet to be done before the physician can always be assured that the immunity undoubtedly conferred for some time upon the mother by bearing a syphilitic child is really enduring, and whether the occurrence of active lesions of secondary syphilis in the child toward the end of the nursing period might not prove an indication for the substitution of artificial feeding for the breast before the usual time for weaning.

THE COMPLETE OPERATION FOR CANCER OF THE BREAST.

Notwithstanding the excellent statistics that such operators as Halsted in this country, Cheyne in England, and Heidenhain in Germany have been able to bring forward as the result of operations for mammary cancer that included the removal of all the lymph nodes that were suspected of infection, not all of the practical operators have been ready to concede that this form of so-called complete operation is the only surgical intervention justifiable in these cases. During last winter there was a series of discussions on this subject before the Royal Medical and Chirurgical Society of London, in which a number of prominent London surgeons

took part. Not a few of the men who do large amounts of operative work still cling to the view that what has been called the incomplete operation may be employed. They object to the term "incomplete," which is a designation, and a very apt one, it would seem, of Mr. Watson Cheyne's invention, and claim that in certain cases the removal of the breast and of such lymphatics as are evidently infected is a radical operation, and the cure often an absolute one.

If anything has been made clear by the recent operative work in mammary cancer it is that on the first operation depends the ultimate prognosis of the case. Operations for recurrence are almost without exception merely palliative, and undertaken only to satisfy the patient's mind for the time being. It seems unfortunate, then, that there should be any hesitancy as to the thorough removal of all tissue reasonably open to suspicion of infection at the primary operation. Halsted's unprecedented results by his complete method are well known in this country, and show how much has been gained by radical removal. Since 1890 Cheyne has operated twenty-one times for mammary cancer, and twelve of his patients lived more than three years after the operation. Nine of these are still alive, six to nine years after the operation, and of the three who died only one is known to have died of cancer. What a difference between these results and those of the day not much more than ten years ago, when Billroth said that he was not sure that he had ever seen a patient with mammary cancer cured by operation!

There is still room for improvement in the matter of surgical interference in these cases, and the frequent references made in recent surgical literature to Halsted's suggestion that the supraclavicular as well as the axillary glands will have to be thoroughly removed shows the direction which operative advance will take. Most operators at present seem to consider this suggestion too radical, but so did the older surgeons of a few years ago when it was represented to them that it was necessary in every case to clean out the axilla. It seems but a question of time until this new suggestion will be very generally acted upon, and we can then confidently look for a still further reduction of the mortality from cancer.

Dr. Stiles of Edinburgh in a paper on "The Dissemination of Cancer of the Breast and the Necessity for Its Treatment by Extensive Operation" (*British Medical Journal*, June 17, 1899) brings out especially the fact that there are no macroscopic appearances of lymph glands that can be depended on to disclose their infection with cancer in the preliminary stages. "In its initial stage," he says, "cancer of a lymphatic gland gives rise neither to enlargement nor to induration, and the absence of these signs, therefore, does not necessarily mean freedom from malignancy." Even in the axilla, as he points out, lymphatic glands may often simulate fat clumps with only a small margin of glandular tissue, yet this tissue may contain emboli of cancer cells, for it would seem to be by embolism rather than continuity of pathologic process that cancer spreads among the lymphatics. Dr. Stiles then repeats Mr. Cheyne's advice as to thoroughness of the primary operation, and while he does not accept Halsted's views as to the advisability of the removal of the supraclavicular glands unless tissue removed from this region should prove on microscopic examination to be infected, he insists that the fascia of the serratus muscle shall be removed completely in every case, and to do this some fibers of the muscle itself must be taken with it, that the sheath of the axillary vein shall be removed, and the branches of that vein coming from the anterior thorax shall all be exsected in every case, as otherwise the lymphatics that accompany these veins cannot be eradicated with any certainty.

ECHOES AND NEWS

Professor Charles Stoerk, the eminent laryngologist, died in Vienna on September 14th.

Typhoid Fever in Madrid. — Fifty-nine cases of typhoid fever were reported in Madrid in one day — September 15th.

Deaf-Mute Congress. — An International Congress of Deaf-Mutes is to be held in Paris during the Exposition. The first school for deaf-mutes was opened in Paris in 1750.

Plague Suspects in Falmouth. — A Norwegian vessel which arrived at Falmouth, England, on September 16th has been quarantined because it is feared there are several cases of bubonic plague on board. Four persons died on the voyage.

The Pope's Illness. — It has been rumored that the

Pope is seriously ill. Dr. Lapponi states definitely that His Holiness is not even ill enough to require the attendance of a physician at the Vatican. The Grand Old Man of Rome continues to accomplish more work than many a man half his age.

Dreyfus Very Ill.—It was reported on September 16th that Dreyfus' health has deteriorated greatly since the verdict of the court-martial was rendered. In spite of his physical weakness he has maintained his calmness and courage. The Government, evidently fearing the disgrace his death would entail, pardoned him on September 19th.

Departure of the "Relief."—The Hospital ship "Relief," with surgeons, one hundred members of the Hospital Corps, twenty women nurses, and medical supplies, sailed from San Francisco for the Philippines on September 14th, notwithstanding that the local inspectors of steamships had condemned the vessel in so far as carrying passengers across the Pacific is concerned. The "Relief" will stop at Honolulu and at Guam.

Abstract Card Catalogue of Physiology.—According to *Science* it is understood that the Boston Public Library will undertake, during the coming winter, the publication of a card catalogue of physiology, the cards to contain not only the ordinary bibliographical information but also brief abstracts of the papers. The plan originated in the Physiological Department of the Harvard Medical School, and Professor W. T. Porter will be responsible for securing or preparing the abstracts.

To Outwit the Quinin Trust.—There is a likelihood of a breaking down of the quinin trust organized by German manufacturers through a movement said to have been started recently by leading cinchona planters of Java for the purpose of keeping the raw material out of the hands of the syndicate of manufacturers. There seems moreover to be no good reason why the United States should not get both the cinchona bark and the sulphate of quinin direct from Java, and thus avoid the trust.

A Woman Who Graduated in Medicine Eighty Years Ago — The honor of granting the first degree in medicine to a woman does not belong to this end of the century. The University of Paris eighty years ago made Madame Boivin a doctor of medicine. She proved herself worthy of the degree not only practically but in a literary way, and besides membership in French and foreign scientific societies, she held an honorable position under the government as chief inspector of a home for convalescents. She died in 1841.

Increase of the Medical Profession in England.—The London *Lancet*, September 2, 1899, says: "During the last ten years the number of qualified British practitioners has increased by about twenty-two per cent., whereas the increase of the population has been only at the rate of 7 5 per cent. According to the Medical Directory there are enough practitioners in England to provide a medical attendant for every 1272 people, men, women, and children, a state of affairs which clearly makes it impossible for all the medical men to earn a decent livelihood."

The Yellow-Fever Situation.—This is much improved. Toward the end of last week there was a movement among the towns of the States of Mississippi and Alabama to quarantine against New Orleans and some other Mississipp River places, but the movement did not spread to any extent and the feeling generally is more confident that further outbreaks of the disease in the Mississippi region are not to be anticipated. At Key West the disease is well in hand and no further accounts of the development of yellow fever in people who have left the city are heard.

The Opium Habit among Asiatic Europeans.—The opium habit prevails among Europeans in the East to an extent which is appreciated only by those who are brought into contact with its victims. In view of this fact the announcement by McLeod of Shanghai that it is possible to cure the habit by the administration of sodium bromid is indeed welcome news. He gives the drug in two doses of two drams, in solution, every two hours for the first two days, and one dram on the third day. Three ounces of the drug in all will probably suffice in most cases.

French Scientists Welcomed. — The President and about 300 members of the French Association for the Advancement of Science arrived at Dover, England, September 16th, on a visit to the British Association, which was in session there. The latter had been urged to give the French Association the cold shoulder on account of the Dreyfus affair. Instead, the reception was most cordial. The French President kissed President Foster, many congratulatory speeches were made, feasting preceded the scientific work, and an ecstatic state of things prevailed generally.

How Soldiers' Feet Are Cared for in England—The importance of the care of the feet of soldiers can scarcely be overestimated. The fact that during the maneuvers on Salisbury Plain last year a large number of men were placed on the sick list on account of some slight trouble with their feet led to the formation of classes among the non-commissioned officers for the purpose of instruction in the art and science of chiropody. The men are not only taught to look after their feet, but are instructed in the prevention and cure of corns, bunions, ingrowing toe nails, chilblains, blisters, etc., slight ailments it is true but any one of which if allowed to go unrelieved, will incapacitate a man for much marching.

Post-Graduate Study in London.—In correction of a recent announcement in the Students' Number of the *British Medical Journal*, the dean of the Post-Graduate College of the West London Hospital writes to say that not only are courses of lectures and demonstrations in the wards given by the staff of the hospital, but that the practice of the West London Hospital is reserved exclusively for post-graduates, and accommodation in the shape of lecture, reading, and writing-rooms are provided for their use. That this undertaking has met with

success is proved by the fact that nearly 100 medical men from all parts of the world have taken out tickets for study at the college during the past twelve months.

The Plank Bed in England.—One of Her Majesty's judges, Mr. Justice Matthews, has recently denounced the use of the plank bed in prisons in the strongest language. Placing a prisoner after a hard day's work upon a bed of planks with nothing under him but a single blanket and sheet, is a relic of the barbarities of the Middle Ages and on a par with the rack and thumbscrew. Yet according to the present law in England it is a necessary part of punishment with hard labor. A convict surgeon of long experience has expressed the opinion that sentences of four months, the first month on a plank bed, have produced more permanent injury to the health of prisoners than far longer sentences without the plank bed.

Concerning Quacks.—The "Annual Convocation of the Faith-Curists" opened on September 15th at the Sanctuary at the foot of Chapel avenue, Jersey City, and will continue for ten days. On September 17th a number of new converts were made, and many wonderful cures were reported. A man who had been an imbecile and a bodily wreck up to his thirty-second year is alleged to be "all right now," etc. The West Virginia State Medical Society is prosecuting Christian Scientists and all other quacks who engage in the practice of medicine without a degree from some reputable college. A committee has been appointed to raise funds out of which will be paid the expense of driving all illegal practitioners from the State.

Death of Dr. Cruice.—Dr. Robert B. Cruice of Philadelphia died suddenly on September 14th in the arms of a patient, General Pennypacker, whom he was visiting professionally. Dr. Cruice had been prominent in Philadelphia medical circles for thirty years. He was graduated from the University of Pennsylvania in 1859, and in 1861 entered the army as assistant-surgeon, attached to the Thirty-eighth Pennsylvania Volunteers. He served until 1863, when he was compelled to resign on account of injuries received by his horse falling on him. After the war Dr. Cruice returned home and became identified with the leading Philadelphia hospitals as surgeon. At the time of his death he was a Fellow of the College of Physicians.

Consumptives in California.—The California State Board of Health passed a resolution on September 14th declaring that plans should be considered for establishing a quarantine against human beings and domestic animals with tuberculosis entering the State. It would be astounding indeed if the plans proposed concerning human beings should mature. Dr. D. D. Crowley, in introducing the resolution, declared that statistics show tuberculosis to be spreading rapidly among native-born Californians. He referred to the constant danger from the large number of consumptives who seek Southern California for their health, and declared that the protection of the State's inhabitants is of more value than the cure of a small percentage of invalids. All this is practical Christianity with a vengeance.

Position of Women in Germany.—The struggle to determine the position of women in Germany continues unabated. After the students at Halle protested against the admission of women to the medical courses of that university, the Woman's League of Berlin submitted an address to the Federal Council of the Empire asking for the full admission of women to the medical departments of the universities and to the examinations in medicine. So far as the Universities of Giessen and Strasburg are concerned, this has already been granted. The government of the Grand Duchy of Baden is equally pronounced in their favor. In Berlin the administrators of orphanages have employed women in certain offices. On the other hand, the administration of the railways has just decided that any woman employed in connection with them shall receive from $25 to $50 less than that received by men for the same work.

Inspection of Fruit Syrups.—At the beginning of September, according to its official announcement, the Board of Health of New York City took upon itself the duty of allowing only syrups made from fruit-juice to be dispensed from soda-water fountains and other dispensaries of drinks. So far we understand very little has been found that required correction. It is supposed, however, that dispensers of fictitious flavoring syrups took warning, and for the time being at least, are not risking detection. It is well known that large quantities of so-called fruit-syrups are manufactured without the slightest tincture of fruit-juice entering into their composition. The products used in their manufacture are various aromatic substances from the coal-tar series of compounds, and a number of scents obtained in the same way. It is proposed, however, by the health authorities to break up the practice of dispensing any such materials in this city.

Butter of Cows Fed on Cotton-Cake.—Cotton-cake is the mass of substance that remains after the cotton-seed oil is expressed under heavy pressure from the seeds of the cotton plant. It was long considered as a waste product, but of recent years it has been proposed to use it as fodder for cows, and the attempt has been successfully made. The *British Medical Journal*, in a recent issue, says: "Experiments made at Wye and in the laboratory are held to have proved beyond doubt that the characteristic constituent of cotton-seed oil passes into the milk of cows fed upon cotton-cake. Certain samples of butter examined during the year gave reactions for cotton seed oil, but the amount indicated was held to be not more than might be due to feeding on cotton-cake." This observation if confirmed by further investigation and other observers will make still more difficult the already tedious task of testing butter for foreign ingredients and deciding as to its adulteration.

Residual Light Effects on the Retina.—The following personal observation of the greatest of living scientists

seems worthy of special notice: Lord Kelvin writes to *Nature* from Aix-les-Bains, under date of August 7th, as follows: "Last night, during a thunderstorm of rare severity, in which brilliant flashes—single, double, triple, or quadruple—followed one another at intervals often of not more than a few seconds of time, I was surprised to see, with great vividness, on a suddenly illuminated sky, two nearly vertical lines of darkness, each of the ordinary jagged appearance of a bright flash of lightning. I remembered to have seen two real flashes of just the same shapes and relative positions, and I concluded that the black flashes were due to their residual influence on the retina. I turned my eyes quickly from the dark sky outside to an illuminated wall inside the house, and I again saw the same double dark 'flash,' which verified my conclusion in an interesting manner. The fatigued part of the eye failed to perceive the brightness of the sky in the one case and of the wall in the other."

The Color of Water.—As water and its natural color are the basis for certain comparisons in medical chemistry, the following note from Professor Spring, as given in the *Scientific American* for September 2, 1899, will be of special interest: The author reports on his experiments of many years to explain the color of the water. He has come to the conclusion that a pure blue is the natural color of water, for when we look through a long tube filled with distilled water against a brilliant white surface, a pure blue is seen, such as is shown by the Lake of Geneva in quiet weather, a color which is not influenced by superficial or interior reflection. When pure water becomes slightly turbid by extremely finely divided white or colorless particles floating therein, they reflect, even in the case of ground mountain crystal, a yellow light, which unites with the natural blue into a brilliant green color, such as is exhibited by the Neuenburg and Boden Lakes. The peculiar facts established by various observers, that the water of ordinarily green lakes turns perfectly colorless at times, is not due to a clarification, but, on the contrary, to an influx of a reddish mud, colored by ferric oxid, which completely neutralizes the green.

Hardening Plaster of Paris.—A German patent has been granted for the treatment of articles of plaster of Paris with an aqueous solution of ammonium borate for the purpose of hardening them and making them impervious to water. As such a process will be useful to orthopedic surgeons not only in making plaster splints last longer, but especially because it may serve to lessen the wear and tear on plaster bandages that occurs now whenever they come in contact with the discharges from the patient, we have thought it worth while to call special attention to the method. The hardening liquid may either be mingled with the plaster when it is being prepared, or it may be applied to the surface of the bandages with a brush after they have been put on. The solution is prepared by dissolving boracic acid in warm water and adding thereto sufficient ammonia to form the borate which remains in the solution. The manner of using the solution is thus described: The saturation of the gypsum or painting of the plaster of Paris is carried out in the cold. The objects are subsequently rinsed off and dried. The surface becomes very hard after two days and insoluble in water, while the induration in the interior advances more slowly.

Progress of the Malarial Investigation in South Africa.—In last week's issue our London correspondent reported that the expedition sent to South Africa by the Liverpool School of Tropical Medicine has reported complete success in identifying the species of mosquito responsible for the dissemination of the malarial parasite. The *British Medical Journal* for September 2, 1899, announces editorially that it has received a telegram from Surgeon-Major Ross, forwarded from Las Palmas, containing the important information that in the genus *Anopheles claviger* he has succeeded in cultivating the quartan form of the parasite. The *Journal* says further: "Through the investigations of the Italians we were already aware of the fact that the tertian and summer-autumn parasites affected the anopheles as their host; but now Ross' discovery proves that the anopheles can also become the intermediate host of the quartan. The cycle had hitherto only been completed for two of the three differentiated parasites of malaria, leaving the quartan to be dealt with. This Ross has done, so that the anopheles is now proved to be an intermediary host for all known malarial parasites. Another important point settled by Ross' investigations is the fact that the quartan parasite is to be met with on the West Coast of Africa. The prevalent form of fever on the West Coast is the summer-autumn, the tropical malaria of Koch, and, although the tertian parasite has been found there in a few cases, we had no definite knowledge that the quartan parasite existed in these regions. We congratulate Major Ross on the excellent work he has done." It would seem that the malaria problem, and with it the making of the tropics habitable for the white race without the frightful mortality which has so far been necessary for the acquirement of acclimation, is near at hand. This pleasant prospect is practically all the result of the work of English and Italian pathologists, and they deserve the highest praise.

The Plague Situation.—At Oporto there have been no new cases and no deaths for some time. On the whole the epidemic seems to have been a very mild one; though the disease existed in the city for some three months there were in all less than eighty cases reported. The *British Medical Journal*, commenting on this mildness of the epidemic says: "Unfortunately this is no criterion as regards the future virulence, the recurrence, or the continuance of the disease. We are rich in the literature of the behavior of plague, and one thing which stands out more prominently in this disease than in any other is the inveteracy with which plague clings to any city or district where once it has established itself. Hong Kong, now in the throes of its fifth or sixth outbreak, is an example of this, and it is the chief example we possess in modern times to guide us in our knowledge, or to indicate the behavior, of plague. Poona, in India, rejoiced in the speedy disappearance of the initial visit of plague,

only to be cast down by the recurrence of an outbreak of increased virulence and of wider extent." The *Journal* counsels, therefore, the most strenuous efforts at complete eradication of the disease before there should be the slightest relaxation of precautions against the spread of it in Europe. At Alexandria there has been an occasional case reported during September at times when further outbreaks of the disease seemed surely at an end. At Poona the disease continues almost with unabated severity. A very virulent form of plague is raging there, and Lord Sandhurst, the Governor of Bombay, has visited the city. Lord Sandhurst regrets the spread of plague, in spite of measures taken to combat it. He draws a dark picture of the future in many parts of India, where the crops have failed owing to the failure of the monsoon rains, and that they have to face not only plague, but a famine of more or less severity. In Russia the situation is so much improved that all further danger seems at an end. The plague-stricken village of Kolobovka, in the Astrakan district, has been completely enclosed by a rigid military cordon. The first case of plague in the Kolobovka occurred on July 23d of this year, and since then twenty-four cases of plague have occurred with twenty-three deaths. The last death occurred on August 24th. It has not been ascertained whence the disease came, and a careful report on the surrounding districts by Prince Oldenburg states that nowhere in the neighboring regions is there any suspicion of plague. At Hong Kong plague matters remain in statu quo. Twenty deaths from bubonic plague took place there last week. Eighteen new cases have been officially reported. At Newchwang the situation is worse than before, and there seems to be good reason to think that the disease is being disseminated throughout Manchuria. The Russians fear that there will be a scare among the Chinese working on the Trans-Siberian railroad between Taheuwan and Newchwang. It is thought that it is the gathering of laborers for this work that has brought the plague from Hong Kong, Amoy, Canton, and other infected ports. It is at Newchwang they all disembark on their arrival. Fresh cases of plague are reported as having broken out at Magude, a little port not far from Lorenza Marques on Delagoa Bay, East Africa. At Mauritius there is not as yet any diminution of the virulence of the disease, over fifty cases a week are being reported and about thirty-five deaths. As we go to press the daily papers announce that the bubonic plague has broken out at Assuncion, the capital of Paraguay in South America. Assuncion is a city some sixty miles above Buenos Aires on the Paraguay River and has a population of about 30,000. The possibility of the truth of the report cannot be denied, though it may prove only a newspaper canard. It must be remembered that the plague existed at Oporto in Portugal for nearly two months before it was officially reported to other governments. There are, too, certain slow running cases of the plague that succeed in getting beyond even a watchful quarantine, which is not very likely to have existed in this case (when the ten-day limit for the development of the disease is accepted too literally).

MEDICAL MATTERS IN NEW YORK.

HEALTH BOARD PROVISIONS FOR THE DEWEY CELEBRATION—DR. SULLIVAN LOSES A FOOT—TO STOP THE SMOKE NUISANCE—IMPORTED LEPROSY—HOME FOR SELF-SUPPORTING WOMEN—A PAUPER WITH A BANK ACCOUNT—NEW HARLEM HOSPITAL—UNITED HEBREW CHARITIES—THE AMENDED DISPENSARY LAW.

PRESIDENT MURPHY of the Health Board has directed that a sanitary inspector be assigned to each of the various elevated railroad stations during the Dewey celebration, to see that the rooms and the means of egress and access to the trains are kept open, that no overcrowding takes place and that the community is protected.

Dr. Joseph Bryant of Manhattan, assisted by Drs. J. C. Kennedy and J. P. Murphy of Brooklyn amputated Dr. John D. Sullivan's right foot on September 12th. Dr. Sullivan is a Brooklyn police surgeon. When a child his foot was injured and he had limped ever since. This summer erysipelas attacked the member and necessitated the operation.

The Merchants' Association laid before its counsel on September 16th the result of the work of the special committee which made a tour the city for the purpose of noting the factories, buildings, tugs, and steamboats burning soft coal. An opinion has been rendered to the effect that all of the parties referred to in the memorandum could be proceeded against for burning soft coal—as committing a public nuisance. The government of bays and water highways is one that would come more particularly under the direction of the Federal officers, but no doubt these officers would work in harmony with the Board of Health in the prosecution of the delinquents.

A New York physician has written a letter to one of the lay dailies in which he "sounds a warning note" on the subject of imported leprosy. The writer cites the conclusions of the Berlin Lepra Conference to the effect that leprosy is contagious, incurable, and due to an organism existing only in man, that it is propagated by human currents, and that isolation is the only remedy. The problem, therefore, considers the writer, should be transferred from medical hands into Government hands, and is one "for the public press and not for the medical press." Several years ago there was a leprosy scare in this town. A law was passed in obedience to which some six unhappy creatures were isolated on North Brothers' Island. Soon the public got over its fright. Then some soft-hearted official, touched by the sight of these half dozen miserable human beings practically marooned upon this island, had a rowboat put surreptitiously upon its shore. To have freed them would of course have been an outrageous violation of the law. So, like the Arabs, they quietly stole away; and so the whole business ended.

The Regina Angelorum, a home for self-supporting working girls, was opened at 946 Lexington avenue on September 18th. It will be non-sectarian, although conducted under the auspices of the Catholic Church. The Sisters will give special care to the sick.

Eleanor Oldenbuttle, a widow, thirty-five years old, has lately died at Bellevue Hospital from Bright's disease and alcoholism. She was believed to be destitute until the Charity Organization Department notified Superintendent Blair of the Outdoor Poor Department that the woman had two large bank accounts.

President Keller of the Charities Department has asked the Board of Estimate to include $474,500 in his appropriation for 1900, for alterations and repairs to buildings. This sum is $274,500 in excess of the amount appropriated for the same purpose last year. The Commissioner considers that every cent he asks for is needed. Among other things, he intends to build a new Harlem hospital, which will cost $150,000. The entire amount asked for by Mr. Keller is $1,874,244, an increase of $293,512 over last year. All the Tammany officials have applied for increased appropriations, but, by all reports, Mr. Keller is one of the few who requires the increase, he asks, for strictly legitimate purposes.

The amended dispensary law for this city will go into effect on October 1st. A résumé of the provisions, therefore, may not be *mal apropos* at this time. A dispensary is declared to be any person, corporation, institution, association or agent whose purpose it is either independently or in connection with any other, to furnish, at any place or places, to persons non-resident therein, either gratuitously or for a compensation determined without reference to the value of the thing furnished, medical or surgical advice or treatment, medicine or apparatus, provided that the moneys used by and for the purposes of said dispensary shall be derived wholly or in part from trust funds, public moneys, or sources other than the individuals constituting said dispensary and the persons of said dispensary actually engaged in its distribution.

Each applicant before he receives a license, must swear that the dispensary is for the benefit of the public, and no one can conduct a dispensary without this license. The license shall not dictate which school of medicine shall be practised in the dispensary, but the State Board of Charities is empowered to visit and examine every dispensary and to revoke a license after due notice, if it finds that the law is being violated. The application for revoking shall be made to the Supreme Court.

No dispensary is permitted to be opened in a drug-store or in a tenement-house.

No one, except a duly licensed person or society, shall display any sign which would indicate the existence of a dispensary. Any person who violates the law is guilty of a misdemeanor, punishable by a fine of not less than $10, nor more than $250. The same fine is fixed as the punishment of any one who obtains dispensary relief by false representations.

CORRESPONDENCE.

THE DIDACTIC LECTURE—A REPLY.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your issue of September 16, 1899, a correspondent quotes a communication of mine made to your columns several months ago and quite misrepresents my attitude toward the Didactic Lecture. Any one reading his letter without seeing mine would imagine that I do not believe in clinical and illustrative teaching and that I advocate the dryest form of didactic instruction. This is quite contrary to the fact. There are didactic lecturers and didactic lecturers, and one who does not know how to teach will abuse his opportunity. The point which I desire to emphasize is that the didactic lecture cannot be absolutely expunged from the roster of the medical school as some would have us believe, although of course such lectures should be much less numerous than they have been in years past.

I would not write this letter were it not that I do not wish to be placed on record by someone else, as advocating something which I do not advocate, and if your correspondent had as much difficulty in understanding didactic lectures as he has had in understanding what I have written, I do not wonder that he is utterly opposed to them.

In medical teaching, as in practical therapeutics, the safe rule is not to follow the enthusiastic advice of persons representing either side of a question; by following a well-guided middle course we can obtain those results which can be reached by adherence to the old rule of moderation in all things.

Very truly yours,

H. A. HARE.

PHILADELPHIA, SEPTEMBER 16, 1899.

MEDICAL MATTERS IN CHICAGO.

PANDEMIC OF INFLUENZA—REST-CURE HOME—MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

CHICAGO, September 18, 1899.

SINCE the last great pandemic of influenza, which reached its climax in Chicago in the epidemic of 1891–92, there has been no period altogether free from the disease, and in this city it appears to have become permanently domesticated. In 1891 there were 336 deaths from influenza reported to the Health Department; in 1892 there were 103; 88 in 1893; 51 in 1894; 165 in 1895; 17 in 1896; 15 in 1897; 281 in 1898; and 304 up to the close of July, 1899.

While these figures are not, in themselves, very alarming, they have a serious significance for the student and worker in preventive medicine. It is true that the influenza epidemic of 1891 added less than one and a quarter per cent. of deaths from influenza to the deaths from all other causes, and the 304 influenza deaths during the first six months of this year are only two and a quarter per cent. of the total deaths from all causes. But the indirect results of the epidemic disease, through its fatal complications of other diseases, swelled the total mortality-rate of 1891 by seventeen per cent. over the average mortality-rate of the previous five years, during which there was no influenza. The increase of the death-rate this year is not so marked, but it is still more than fourteen per cent. greater than the average of the previous five years, the lesser comparative increase being fairly at-

tributable to the prevalence of influenza, in a minor degree, during the previous five-year period.

There has been a marked preponderance of deaths among females from influenza as the sole or chief cause, the proportions being 58.4 per cent. of females to 41.6 of males; while the proportions are very nearly equal in the deaths of which influenza was assigned as a complication or a contributory cause. The proportions for both groups are 54.1 per cent. females, 45.9 per cent. males. During this period, January 1st to April 30th, inclusive, there were 9457 deaths from all causes, influenza included, of which number 5184 were of males and 4273 of females, the sex proportions among the influenza deaths and among the deaths from all causes being almost exactly reversed, 54.8 per cent. males, 45.2 per cent. females for the latter, and 54.1 per cent. females, 45.9 per cent. males for the former.

Fifty per cent. of the total deaths from influenza as the chief cause were among persons over sixty years of age, and 22 per cent. of the total were of persons between seventy and eighty years old.

The will of the late Judge Richard Prendergast, who died of pernicious anemia, provides for the foundation of a rest-cure home for those who are suffering from insomnia and nervous troubles. This home is to be located at Wheaton, Illinois, and one condition on which its establishment is based is that it be known forever as "St. Winifred's Rest," in honor of the wife of the testator.

The official program of the meeting of the Mississippi Valley Medical Association, to be held in this city October 3d to 6th, has been issued, and 35,000 copies of it distributed. Of 62 papers listed to be read, 29 are assigned to the medical, and 33 to the surgical, section. The general sessions will be held in Handel Hall on Randolph street, opposite the Masonic Temple. The medical and surgical sections will meet in the lodge rooms on the eighteenth floor of the Masonic Temple.

This society was originally known as the Tri-State Medical Society of Indiana, Kentucky and Illinois, and from its foundation has had a successful career. Its early meetings were well attended by the States represented in its membership. Its organization was due largely to the efforts of Dr. B. F. Swafford, its first president, and Dr. G. W. Burton, who was its secretary for eight years. At the meeting held in Indianapolis, as the attendance was no longer limited to the three States, it was unanimously decided to change the name of the society, and a committee brought in the name, "Mississippi Valley Medical Association." It was originally intended to limit the membership to members of the profession residing in the Mississippi Valley, but of late years there have been in attendance physicians east of the Alleghanies, and as far West as Utah. In point of numbers, this Association is second to the American Medical Association. One of the largest meetings in the history of the society was held in Louisville, when there were so many papers on the program that it was necessary to divide the meeting into two sections, medical and surgical. This had been attempted at previous meetings, but usually most of the papers were read in general session. The annual addresses have been special features of the Association for many years.

At the meeting in Louisville more definite organization was adopted, including constitution and by-laws, which put the Association upon a sound working basis. The most important change was made in the membership, which became continuous, dependent upon regular payment of dues, two-years' non-payment causing forfeiture.

Chicago has many excellent clinical teachers who have almost without exception consented to aid the Committee of Arrangements in making the coming meeting interesting and profitable. There will be a series of public clinics from September 25th to October 2d, inclusive, and from October 7th to October 14th, inclusive. The clinics, about 140 in number, will be held especially for the members and guests of the Association. The Committee on Hospitals will have it for their special duty to make visitors welcome at the various institutions, and to assist as far as possible in making the clinical features available. The clinics have been so grouped that visitors may spend the entire forenoon at one hospital and the afternoon at another. Where the time of clinics overlaps the committee has, so far as possible, aimed to parallel clinics on medicine and surgery, feeling that those who are interested in surgery can put in the most of their time on that subject, while those that are interested in internal medicine need not attend the surgical clinics.

SCIENTIFIC MEDICAL JOTTINGS FROM AMERICAN TROPICAL COUNTRIES.

TWO CASES OF URETHRAL CALCULI.

El Progreso Medico of Havana for August, 1899, in the report of a recent meeting of the Sociedad de Estudios Clinicas of Havana gives the details of two cases of urethral calculi. In both there had been considerable difficulty of urination extending over long periods of time, in one from early childhood. In one of the cases a small very hard tumor presented in the perineum; in the other the diagnosis was made with a sound. The stones were crushed by a small lithotrite and the fragments removed with urethral forceps. In one of the cases, after the removal of the calculus, a stricture developed. It was dilated but recurred almost immediately. A second dilatation was no more successful, and it was found on careful examination that a partial membranous diaphragm was obstructing the urethra where the calculus had been. Division of this with a urethrotome and subsequent dilatation was followed by the prompt disappearance of all symptoms and they have not recurred.

RECOGNITION FOR CUBAN MEDICAL HEROES.

El Progreso Medico is also publishing a series of photographs and biographical sketches of the medical men who fell serving the Cuban cause during the late revolution against Spain. The August number contains a sketch of Dr. Federico de la Torre y Latte, who fell at the engagement at Las Taironas in the Province of Pinar del Rio, January 17, 1896, while bravely fulfiling his duties as a surgeon on the firing line. His conduct dur-

ing all the time of his service with the Cuban army had been marked by such self-forgetting courage and unpretentious patriotism that his death called forth from his commander a letter to his friends full of the loftiest panegyrics. Cuba does well to honor her non-combatant heroes and the medical profession is to be complimented in not allowing the memory of heroic brothers to die out.

A DISEASE SPECIAL TO MINERS.

In the *Revista de Anatomia, Pathologica y Clinicas* of Mexico for June 15, 1899, Dr. Thomas Chaves describes a disease which has been noted among the miners in the gold and silver mines at Guanajuato, Mexico. The mines are very deep, among the deepest in the world and at the same time the most productive. The disease which attacks the miners has two forms, acute and chronic. In both forms a blood change with the development of an intense anemia is the most prominent symptom. In the chronic form the progressive anemia is followed by headache, vague pains all through the body, loss of appetite, and tendency to fainting spells, while the blood picture that develops is like that of leucemia. In the acute form of the disease the first symptom is a fainting spell with which the men are taken shortly after their entrance into the mine, though they may have seemed in excellent health just before going in. The faint is followed by intense headache, rumblings in the ears, thirst, nausea, at times coughing spells and further tendency to faint. Anemia rapidly develops if the patient is not carried off by the failure of some important organ and the leucemic picture of the chronic form asserts itself.

Dr. Chaves attributes the symptoms noted to an intoxication with gases from the minerals so recently uncovered and the undergoing often, therefore, of rather rapid changes in the presence of the oxygen of the air. Analyses made of the air in the mines showed that it contained distinct traces of antimonio-arseniuretted hydrogen and sulphoseleniuretted hydrogen. At times almost 1 per cent. of each of these mixed gases was present.

One of the mines mentioned is more than 2000 feet deep and it is to be remembered that owing to the compressibility of air, the atmosphere of a deep mine is very dense. The pressure is perhaps enough to disturb internal respiration as does working in a caisson unless precautions are taken. Whether this may not have an influence in the production of the symptoms described is worth investigating. We have in this country, besides in certain of the gold and silver mines in the copper mines an excellent opportunity to study the effect of condensation of the air at great depths on the respiration and general health of the miners. An investigation of the effects would be most interesting.—EDITOR.]

MINER'S ANGIOLEUCITIS.

In the same number of the *Revista de Anatomia, Pathologica y Clinicas* is a description of a form of angioleucitis peculiar to workers in mines. It does not occur after severe wounds nor does it follow amputations or surgical operations, but begins in a slight scratch or lacerated wound. It is always followed by suppuration for which the most successful treatment is free incision with the removal of affected glands. The constitutional symptoms of the disease are very severe. There is high fever, nausea and vomiting, followed in the worst cases by delirium and convulsions. The affection attacks the robust and healthy as well as the weak and sickly. Very often the site of the original injury does not suffer much from inflammation. Especially is this true when it is some slight injury of the fingers. In this case the lymphangitis usually begins at the wrist and spreads up the arm. Cultures of staphylococcus albus and aureus have been obtained from the pus, but there would seem to be some more virulent micro-organisms at work, very probably a pus-producing anaerobic microbe, if the usual character of the inoculation is to have its proper weight. The angioleucitis set up practically never disappears by resolution, though this termination is not infrequent in the ordinary forms of lymphangitis. In all cases in miners suppuration was looked for and did occur practically always.

ENLARGEMENT OF THE LIVER AND SPLEEN IN ANCHYLOSTOMIASIS.

This interesting parasitic disease was introduced into Brazil from Europe just as it was also brought to this country. In Brazil, however, the general neglect of sanitary precautions among workmen, in soil generally, as in mines, tunnels, brick-yards, etc., has led to the extensive spread of the disease there, so that now a number of cases of the affection are reported from various parts of the country. Dr. Pedro de Almeida Magalhaes, in the *Revista Medico de San Paulo* (a Portuguese medical journal of Saint Paul, Brazil), Anno II., No. 6 and 7, reports thirteen cases of the disease that have come under his observation. He has been struck by the fact that the liver and spleen in all of his cases could be clearly demonstrated by percussion to be enlarged. In three cases in which there was absolutely no malaria and no alcoholism in the history, this condition of enlargement of the liver and spleen was especially studied. Dr. Magalhaes thinks that it may be considered an invariable accompaniment of anchylostomiasis, at least in its severer forms. He considers that this disease is often mistaken in tropical countries for a chronic malarial cachexia and advises the careful microscopic examination of the stools in all cases of severe malaria. The characteristic eggs of the parasite betray its presence in the intestine and makes the diagnosis easy and certain.

A CASE OF FULMINANT MALARIA IN CUBA.

In *El Progreso Medico* of Havana (Anno IX., No. 2, August, 1899) there is report of a case of pernicious or fulminant malaria such as intending medical immigrants to the island may expect to see occasionally. The patient was taken with hematuria one evening, vomited blood next day and developed a temperature of 104.5° F. Icterus set in and rapidly became deeper and the patient died the next afternoon. For some hours before his death his temperature had been falling, reaching before the end 94° F. Dr. Jorge Le Roy y Cassa, who reports the case, does not believe in the administration of quinin for malaria and thinks that it is often the cause of the so-called

malarial hemoglobinuria, so none of that drug was used. Injections of Hayem's serum solution (practically normal salt solution) were made subcutaneously with the idea of washing the toxins out of the blood, but seemed to produce no effect. That the case was not one of yellow fever the autopsy and the fact that the patient was a mestizo, *i.e.*, a mixed-breed Cuban, all of whom are supposed to be immune to yellow fever, and that no yellow fever had been known to exist for a long while in the part of the country from which he came, all seem to show. The writer thinks he could also exclude the idea of this case being either the so-called severe icterus or the bilious fever of hot countries.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held June 21, 1899.

THE President, WILLIAM STEVENS, M.D., in the Chair.

CARCINOMA OF THE LIVER.

DR. J. H. FRUITNIGHT: The case which I desire to report is interesting on account of the difficulty experienced in making a diagnosis. The patient was seen early in the spring, at which time she presented indefinite symptoms. Then came gradual emaciation and failing of the vital powers together with obstinate constipation. By excluding the diseases in which emaciation and exhaustion are the predominant symptoms, we reached the conclusion that the patient was suffering from malignant disease, and, upon examining the organs *seriatim*, we found that the left lobe of the liver extended further to the left than it should and beyond the median line, that its border was sharper than normal, and that its substance was nodular. Two eminent practitioners of this city, who were called in consultation, confirmed the diagnosis of carcinoma of the left lobe of the liver.

ABSCESS OF THE MONS VENERIS.

DR. A. M. JACOBUS: Two weeks ago I was called to see a woman whose family physician had left the city for the summer on the previous day. I found a stout woman, thirty-five years of age, weighing about 180 pounds, with an ice-bag upon the mons veneris. There was a very tender swelling in that region and the patient seemed to be suffering greatly. I was told that a year previously an abscess had appeared there which had been opened by her physician, that it had closed prematurely (as she thought), and caused blood poisoning. The swelling was very hard, twice as large as a door-knob, movable, and appeared to be a localized cellulitis with pus in the center. It was situated over the pubic region between the muscles and the skin. As the patient refused to have it opened, and as fluctuation was not distinct, I ordered the ice-bag removed and flaxseed poultices, as hot as possible, applied every hour and a half day and night, in the hope that the abscess would point and discharge spontaneously. This it did two days later, the pus which was discharged being exceedingly offensive, blood-stained, and amounting to several ounces. The patient had been a widow for five years, and had never given birth to a child. There was no history of venereal disease or of injury, excepting that some four years before she had struck herself at that point against the corner of a table. This accident, however, was not followed by any special symptoms, and it is very doubtful if it had anything to do with the present trouble. No abnormality of the pubes or pelvic viscera could be detected, and no enlargement of the inguinal glands existed. The abscess was in the fat outside of the muscular tissue, as stated, and could be lifted up, showing that it had no connection with anything else. The patient did well and the induration about the sac gradually disappeared, the sinus being kept open with gauze until the last. The case is reported because of its rarity.

DR. P. C. COLE: I saw a somewhat similar case some four weeks ago. The attending physician had made a diagnosis of general peritonitis and appendicitis, and advised the patient to go to a hospital for operation. I incised the abscess and the patient promptly recovered.

DR. S. H. DESSAU: Dr. Jacobus' case reminds me of one seen in my service while connected with the New York Dispensary, in which there was an abscess of the abdominal wall just above the umbilicus. The woman recently gave birth to a child. I believe that these abscesses are now regarded as phlegmons of the peritoneum or localized peritonitis extending through and involving the abdominal wall.

DIPHTHERIA ANTITOXIN.

DR. DESSAU: I have on previous occasions reported to this Society several cases in which I have successfully employed antitoxin in diphtheria. I wish now to report another in which the child died of heart failure on the eighth day after the first injection. I do this in order to show that I am unbiased in my estimation of the remedy. The fatal termination in this instance cannot be attributed to the antitoxin. The case was a very severe one from the beginning. The pharynx, including the tonsils, soft palate, and post-nasal space, together with both sides of the nose, were involved, and the submaxillary lymphatics on both sides were immensely swollen. Five thousand units of the antitoxin were administered in two doses, 3000 and 2000. The child improved promptly, the membrane in the throat cleared up, breathing through the nose became free, and the swelling of the lymphatic glands of the neck subsided completely, but death occurred suddenly from heart failure, as is not uncommonly the case in diphtheria not treated with antitoxin.

DR. ROBERT NEWMAN then read the paper of the evening, entitled

BOTTINI'S OPERATION AND OTHER TREATMENT OF THE ENLARGED PROSTATE.

(See page 397.)

DR. ROBERT H. GREENE: The writer of the paper having requested that we discuss the causes of prostatitis among other subjects, I will say that in 216 cases of urethritis examined by me I found more or less prosta-

titis in more than forty per cent. This would tend to show that urethritis is a very active cause of prostatitis, although, of course, it may be due to other causes, such as sexual excesses, and apparently not infrequently to indigestion, giving rise to excess of uric acid or phosphates in the urine, and causing local irritation. The local treatment of prostatitis is not an easy matter, and often does more harm than good. Attention to the general health will often result in improvement. The patient should take plenty of exercise, and attention should be given to the diet and habits of life. So far as the Bottini method of treatment is concerned, the first case recorded in America was that by Dr. Weber a year ago this winter before the Genito-Urinary Section of the Academy of Medicine. Since then the operation has been performed a number of times by Dr. Willy Meyer and a number of other men, among them Dr. Guiteras, who nas read a paper upon the subject. I am familiar with Bottini's operation, for I have seen Guiteras employ it at the City Hospital in several cases. It is not difficult of performance. It apparently can be improved upon in several respects. First, in regard to the anesthetic. If cocain is depended on the patient will suffer a great deal in a large majority of cases, and it is much better to administer ether. Secondly, in regard to the batteries. Neither the street current nor the storage-battery made by the instrument-makers can be absolutely relied upon; therefore, it is best to provide two storage-batteries or to employ the street-current and have one storage battery on hand in case of necessity.

I am convinced that Bottini's operation can be performed with safety so far as danger to life is concerned; but when it comes to the results obtained this is another matter. In many of the reported cases the history has been very imperfectly recorded. It is hard to tell whether many of them were cases of true prostatic hypertrophy or not. Now, with this condition of enlarged prostate there is a state of congestion which apparently is responsible for a good deal of the enlargement which one feels with the finger in the rectum. For this reason rectal examination alone is not sufficient to determine whether or not the prostate is enlarged. This congestion is sometimes relieved by several different methods, after which there is a marked decrease in the size of the prostate on examination. To my mind, this is the effect which the Bottini operation has; neither more nor less than any other treatment, causing counter-irritation and reducing the congestion of the parts. No permanent good results apparently have as yet been obtained by the Bottini treatment.

Dr. Newman, in closing: I am obliged to Dr. Greene for the remarks he has made. What he says about the battery is very true; it is very difficult to get one that works well. One of my objections to the old Bottini instrument is that the platinum is too large and too soft, and requires a larger battery to heat it than can conveniently be carried about.

In regard to the causes of prostatitis, in addition to those mentioned by Dr. Greene are gonorrhea and injudicious injections of nitrate of silver into the deep urethra.

As to the results obtained by the Bottini method, I would remind Dr. Greene that not all cases are curable, for much depends upon the amount of the hypertrophy, stage of the disease, complications which may exist, and constitution of the patient. I have cured many cases of hypertrophy of the prostate with my galvanocautery sound, some of which have been reported.

REVIEWS.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In Twenty Volumes. Vol. XVI. "Infectious Diseases." New York: William Wood & Co., 1899.

In the perusal of a paper on an acute infectious disease the reader is often impressed by the scientific knowledge shown by the author rather than by the practical character of the description of the disease. This criticism can certainly not be made of the chapter devoted to lobar pneumonia in the sixteenth volume of the "Twentieth Century Practice." It is a scholarly and eminently practical contribution from the pen of Dr. A. H. Smith of New York. We have been much impressed by the excellent clinical description given therein, of the pathology and symptoms of the disease. Pneumonia is not a mere inflammation of the lungs, says Dr. Smith; it is to be regarded as an acute general toxemia depending upon a local manifestation in the pulmonary areas. A good account is given of the results thus far obtained with the antipneumococcic serum and of the difficulties which beset laboratory experimentation along this line. We can highly endorse Dr. Smith's views as to the prognostic importance of the continued accentuation of the second pulmonic sound during the course of the disease.

Professor Netter contributes a well-written and comprehensive paper on cerebrospinal meningitis. The author believes that the warm bath is a specific method of treatment in this affection, and he recommends it as such. Lumbar puncture is a diagnostic, but never a curative method. The article on dysentery is written by Professor Sodre of Rio Janeiro. Considerable evidence is collected to prove that dysentery—especially in tropical climates,—is generally due to infection by the ameba coli.

Dr. Alford Nichols of Dominica, West Indies, writes on yaws and clearly points out the difference between this disease and syphilis. The article on inflammation, by Professor Ziegler, ought, it seems to us, to have had its proper place at the beginning of the thirteenth volume of the series. The article is well written and exhaustive; we regret that lack of space prevents us from discussing some of the interesting theories advanced by the author.

The section devoted to erysipelas is from the pen of Dr. Kiliani of New York. It is concise and contains an interesting account of the methods and results obtained in treating the disease with the antistreptococcic serum. Not all writers are as optimistic as Dr. Kiliani regarding the results to be obtained with the serums as now made.

Thus Koch and Petruschky have shown that the antistreptococcic serum as now made vary greatly both in strength and in efficiency. Dr. L. B. Edwards contributes a short article on simple continued fever, and is followed by Professor Popoff of St. Petersburg, with a detailed and full description of relapsing fever. The historical section is well-written and the bacteriological description is very complete. Several excellent plates illustrate the text.

Dr. Thatcher of New York writes on the etiology and general pathology of typhoid fever, and Dr. Brannan describes the symptoms and treatment of this important disease. An exhaustive description of Eberth's bacillus, its generic characters and the methods in vogue for its isolation is given. Dr. Thatcher places rather a high value on the acid potato gelatin recommended by Elsner as an isolating medium. The pathology of the disease is well described, due importance being given to typhoid fever without intestinal lesions. The symptoms of the disease are discussed with thoroughness by Dr. Brannan. The surgical complications are enumerated, due credit being given to Professor Keen's excellent work on this subject. Special sections are devoted to typhoid fever in infancy, childhood, and old age. The principles underlying the eliminative and antiseptic treatment of the disease, of Woodbridge and of Thistle, seem, to Dr. Brannan "to be sound though the results fall short of the claims of its chief advocates." A good *résumé* of the results thus far obtained with attenuated bacterial cultures and with antityphoid serum is given. In conclusion we may say of the present volume that it is fully up to the standard of previous ones, and reflects credit alike upon the editor and the contributors.

PRACTICAL DIAGNOSIS. The Use of Symptoms in the Diagnosis of Disease. Fourth edition. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia, etc. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

THE fourth edition of this popular work does not differ much from its predecessors in the text, although we note some additions made necessary especially by the advance in laboratory methods of diagnosis. The newer methods of serum diagnosis are fully set forth in this edition and the essential directions for their application are given. The book abounds, as heretofore, in points of the greatest practical value in the establishment of a clinical diagnosis. Several new illustrations and photographs have been added. Of its kind, Dr. Hare's book is certainly unique in its combination of the eminently practical and the necessarily theoretical elements of clinical diagnosis.

THE NEWER REMEDIES. A Reference Manual for Physicians, Pharmacists and Students. By VIRGIL COBLENTZ, A.M., Ph.D., Professor of Chemistry and Physics in the New York College of Pharmacy. Third edition. Philadelphia: P. Blakiston's Sons & Co., 1899.

THE author has included in this little book a consideration of the main synthetic compounds which have appeared since the last edition. As far as has been possible, the chemic composition of the new drugs has been given. The silver compounds attract attention by their number and it is evident that the number of intestinal antiseptics has increased wonderfully. The book is certainly a valuable one for reference to the multiple remedies which the skill of the chemist and the enterprise of the manufacturer is constantly providing.

THE PHILOSOPHY OF MEMORY AND OTHER ESSAYS. By D. T. SMITH, M.D., Lecturer on Medical Jurisprudence in the University of Louisville. Louisville: John B. Morton & Co., 1899.

IN this collection of essays the author attributes too much power, it seems to us, to the forces of Nature in the evolution of memory, omitting factors in its development which are recognized by naturalists as playing important rôles. His essays on "The Functions of the Fluid Wedge" and "The Laws of Riverflow," are certainly extreme in their position and we confess we are unable to criticise them. The essays certainly make interesting reading.

HANDY BOOK OF MEDICAL PROGRESS; a Lexicon of the Recent Advances in Medical Science. By CHARLES WARRENNE ALLEN, M.D., Consulting Dermatologist to the Randall's Island Hospitals, etc., and JACOB SOBEL, A.B. M.D., Dermatological Assistant to the Good Samaritan Dispensary. New York: William Wood & Company, 1899.

ONE can hardly be expected to take this little book seriously. Its title is a misnomer and its plan is a perversion. It purports to be a somewhat more than dictionary explanation of the names and titles of new medical data, alphabetically arranged. In glancing through the pages one will meet, here and there, definitions of a few new names of recently described signs, symptoms and diseases. He will be more apt to encounter paragraphs on titles other than new, relating to subjects by no means recent, and described in words that might fit into a text book a dozen years old; and he will be just as apt to find, chosen with the same inscrutable arbitrariness, descriptions of numerous proprietary preparations. Even in these the work is incomplete.

MATERIA MEDICA, THERAPEUTICS, Medical Pharmacy, Prescription-writing, and Medical Latin. By WILLIAM SCHLEIF, Ph.G., M.D., Instructor in Pharmacy in the University of Pennsylvania. Philadelphia and New York: Lea Brothers & Co., 1899.

THIS handy volume which, from its binding, one might mistake for a collection of poems, is one of the publishers' series of pocket text-books, edited by Dr. Bern B. Gallaudet of this city. They represent, apparently, an amplification of the excellent series of quiz-books published by the same firm and also edited by Dr. Gallaudet.

The work presents no unusual feature. It is a condensation of the essential facts of our materia medica, conveniently arranged. It is scarcely a compliment to the medical profession to print on the title-pages of these

pocket-works and of quiz-books: "A Manual for Students and Practitioners." While some practitioners may from time to time find use for so condensed a reference, they are more apt to turn to standard works for their information. These little manuals are written especially for students, among whom they must find their greatest sale.

PULMONARY TUBERCULOSIS: Its Modern Prophylaxis and the Treatment in Special Institutions and at Home. Alvarenga prize essay of the College of Physicians of Philadelphia for 1898. Revised and enlarged. By S. A. KNOPF, M.D., with descriptions and illustrations of the most important sanatoria of Europe, the United States and Canada. Philadelphia: P. Blakiston's Son & Co., 1899.

THIS work needs no apology for its existence; if for no other reason, the encouragement to be derived from the hopefulness and earnestness that stamp its pages is decidedly wholesome. But it has, beyond this, an intrinsic scientific merit. It is thorough, but not exhaustive; convincing without being argumentative; and original, but carefully avoids all that is not proven.

The author at the outset begs us not to despair in the absence of specific treatment. With the means we have at our disposal tuberculosis is a preventable disease, and, especially in its pulmonary forms, a curable one. Nor is its curability as infrequent or as difficult as is generally believed. The author then devotes himself to the exposition of those methods of treatment best adapted to the cure of phthisis. These, he teaches, are the hygienic, dietetic, respiratory (gymnastic), aero- and hydrotherapuetic and medicinal—usually most successful when carried on in a well-conducted sanatorium, but of paramount importance and of the greatest value even at home.

Both at home and in a sanatorium, careful and constant medical supervision is absolutely essential. To climatic influences the author relegates a secondary rôle, as being of less importance than institutional and hygienic influences. Nevertheless, climatic treatment forms a valuable and often indispensable adjuvant. Several pages are devoted to it; from which the conclusions are deduced that while some climates may be posted as harmful to certain classes of phthisical patients, no climate can be assumed to be beneficial to any individual case without actual trial.

A large part of the book is devoted to illustrated descriptions of the most important sanatoria of Europe and America. A supplementary chapter outlines the author's plans of an ideal sanatorium.

The social problems which tuberculosis entails are succinctly treated of. The public measures essential to the prophylaxis and extermination of human and bovine tuberculosis, as here outlined, are neither complicated nor extremely difficult to carry out. The importance of national regulations—another plea for a national health board—is made very plain. Sanitary tenements for the poor is another prophylactic institution referred to.

The work is not clinical. It avoids an excess of statistics, adding thus to its simplicity and interesting style. It will appeal, as it is indeed dedicated, to all hygienists, and public men, as well as to physicians—for, in matters of public health, the latter can only insure what the former must help to secure.

THERAPEUTIC HINTS.

Treatment of Certain Manifestations of Grip.—Inflammations of the mouth, pharynx, nose, or ears occurring in the course of grip should be immediately and vigorously combated, according to LEMOINE of Lille, as they may otherwise give rise to grave complications. For aphthous stomatitis he recommends irrigation twice a day with Labarraque solution (five per cent.), introducing the irrigating tube nearly to the palate in order to cleanse the entire buccal mucosa. The stomatitis is thus cleared up generally in two days. Similar treatment is used in case of tonsillitis and pharyngitis. For children who object to the taste of the Labarraque solution the following may be substituted:

℞ Ac. lactici . . . . . *m.* xl
Ol. menthæ piper. . . . . gtt. x
Aquæ . . . . . ℥ viii.
M. Sig. For irrigation.

When there is a tendency to tonsillar suppuration the tonsils and pillars of the fauces should be thoroughly swabbed also with the following:

℞ Ac. salicylici . . . . gr. viii–xvi
Spiritus . . . . . q. s. ft. sol.
Adde:
Glycerini . . . . . ℥ i
Aquæ . . . . . ℥ ii.
M. Sig. External use.

For rhinitis a spray of liquid vaselin containing menthol (two per cent.) is employed, treating the nostrils alternately, and afterward a small quantity of ordinary vaselin containing menthol (two and one-half per cent.) is placed at the opening of both nostrils.

For otitis a resorcin solution (two per cent.) is instilled into the external auditory canal, this being the best antiseptic for the purpose in cases of grip. It may prevent suppuration.

Applications for Burns.—

Of first degree:

℞ Zinci oxidi . . . . gr. lxxx
Magnesii carb. . . . ʒ iiss
Ichthyol . . . . *m.* xv–xxx.
M. Sig. External use.

Of second degree:

℞ Zinci oxidi . . . . gr. lxxx
Cretæ prep. } aa. . . . ʒ iiss
Pulv. amyli }
Ol. lini }
Aq. calcii }
Ichthyol . . . . . *m.* xv–lxv.

M. Ft. unguentum. Sig. External use. Change dressing every twenty-four hours.

If inflammatory symptoms are marked cover the affected area first with the powder and then apply the ointment.—*Leistikow.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, SEPTEMBER 30, 1899. NO. 14.

ORIGINAL ARTICLES.

DIPHTHERIA: ETIOLOGY, DIAGNOSIS, PROPHYLAXIS.[1]

BY JOHN DUDLEY DUNHAM, M.D.,
OF COLUMBUS, OHIO;
BACTERIOLOGIST TO THE COLUMBUS DEPARTMENT OF HEALTH.

THE bacillus discovered by Klebs, afterward studied by Loeffler, is all but unanimously accepted by those who are considered authorities and by physicians in general as the real etiologic factor in the production of diphtheria. Not infrequently an article may be noticed from the pen of a talented man[2] who claims that the Klebs-Loeffler bacillus is not the cause of diphtheria because it is not found in every case of the disease, is found in healthy throats, and does not produce the typical disease when inoculated into animals, and, indeed, that the modern doctrine of bacteriology is a gigantic mistake.

There are, it is true, a few cases which present the clinical features of diphtheria in which the Klebs-Loeffler bacillus is not found, but could we eliminate the personal equation, make our technic absolutely perfect, and be assured that the bacilli if present in very small numbers on the false membrane would invariably be secured by the process of swabbing, it is undoubtedly true that the germs would be found in every case of the disease.

The objection against its acceptance, that the diphtheria bacillus is found in healthy throats, is not sound. Even the rigid scientific postulates of Koch do not insist upon such a condition. The Loeffler bacillus when injected subcutaneously into animals does not produce typical diphtheria, but *does* cause pseudo membranes to appear on mucous surfaces. Then again, injection into animals causes paralysis, which in character, localization, and time of occurrence are very like those seen in man.

The most conclusive evidence, however, of the action of the diphtheria bacillus upon susceptible animals is furnished by the personal experience of McFarland.[3] To quote from the account given in his text book: "All possible skepticism of the specificity of the bacillus on my part was dispelled by an accidental infection which kept me housed for three weeks during the busiest season of the year. Without having been exposed to any known diphtheria contagion, while experimenting in the laboratory, a living virulent culture of the diphtheria bacillus was drawn into a pipette and accidentally entered my mouth. Through carelessness no precautions were taken to prevent serious consequences, and as a result of the accident two days later my throat was full of typical pseudo membrane, which private and health-board bacteriological examinations showed contained pure cultures of the Klebs-Loeffler bacilli."

The experiment thus inadvertently inaugurated and carried forward by McFarland furnishes a very conclusive proof of the third rule of Koch in regard to the germ under consideration. It will be remembered that this prescribes that a given organism, when injected into a susceptible animal, must produce the disease.

The notion prevalent in some quarters that sewer-gas is a means of inducing the disease is evidently not based upon scientific truth. Bacteria do not rise from moist surfaces, hence this factor as a source of infection must be disregarded. Another statement by Smith[1] is that diphtheria has been on the increase in spite of the fact that systems of sewerage, in England especially, have been greatly improved.

The dairy, when cared for by persons sick with diphtheria, or by those who harbor the germs in their throats, has been proved to be an important focus for the distribution of the disease. This is well illustrated by cases noted by Howard[2] at Ashtabula, Ohio.

The crowding which is occasioned by life in tenements seems to favor the continuance, as well as the dissemination of the disease.

London shows a marked decrease in the number of cases during the summer or vacation months.[3] This is also true of other cities; therefore the congregation of children in schools is undoubtedly responsible in a measure for the spread of the disease.

The conclusion to which bacteriologists and clinicians have been forced in regard to the diagnosis of diphtheria is that the presence or absence of the

[1] Read at the Meeting of the Ohio State Pediatric Society, held at Springfield, Ohio, May 9 and 10, 1899.

[3] J. C. Thrush, *Brit. Med. Journ.*, August 22, 1896.

Klebs-Loeffler bacillus must be ascertained before an intelligent opinion can be formed as to the nature of the disease.

That the character of the membrane is not a safe guide to a diagnosis is insisted upon by Vierordt,[1] and many others, who have found typical lacunar anginas with the presence of the Loeffler bacillus. These cases often lapse into typical diphtheria, hence the great importance of a bacteriologic examination early in the course of the disease.

The choice of a culture medium for the rapid and accurate diagnosis of diphtheria has been much discussed by bacteriologists. Loeffler's blood serum mixture is in most general use at the present time. With the aid of this medium one is able to make a diagnosis within twelve hours. The method proposed by Ohlmacher, the examination microscopically of the still invisible growth after five hours in the incubator, seems to be quite reliable. During the past year in the Laboratory of the Department of Health of Columbus, forty six cases were examined at the end of five hours, and again at the end of twelve hours. In every instance at the end of twelve hours I found the diagnosis identical with that obtained after five-hours' growth.

Loeffler's blood-serum mixture, in addition to furnishing food for development of the diphtheria bacillus, supplies a nutritious soil for the growth of the staphylococcus and the streptococcus. The latter species sometimes interferes with a proper diagnosis of the case. To eliminate this possible error and to secure a uniform medium, Joos[2] makes use of a serum-agar, upon which the Loeffler bacillus thrives, the streptococcus will not grow, while the staphylococcus shows a meager growth. Upon this medium small colonies of the Loeffler bacillus may be seen after four- or five-hours' growth at body temperature. Colonies of ten to twelve-hours' growth are fully developed, and are much larger than those grown upon the Loeffler mixture. Joos has examined more than 100 cases, both by Loeffler's method and his own. The conclusion is that his method is simpler, equally accurate, and more rapid. If these results are corroborated by other investigators there is no doubt that this newest medium is well-nigh perfect. The medium proposed by Joos is as follows: 300 c.c. of ordinary blood serum; 50 c.c. of normal sodium solution; 150 c.c. of distilled water or bouillon. This is placed in a flask, heated in a water-bath for two or three hours at 60° to 70° C., and the flask is then placed in a steam sterilizer for from half to three-quarters of an hour; 500 c.c. of pepton bouillon and 20 grams of agar, which is dissolved as rapidly as possible, are then added. When the solution is perfect it is at once filtered, hot, and sterilized for a quarter of an hour in the autoclav at 100° to 110° C., after which it is poured into Petri dishes.

Prophylaxis.—The most notable point in a consideration of prophylaxis in diphtheria is that while proper measures have been utilized in the disinfection of apartments and clothing the disease is on the increase. The explanation of this inconsistency is undoubtedly in the well established truth that convalescents and persons associated with diphtheria patients become carriers in their throats of virulent diphtheria bacilli. Healthy persons are then infected by association with these diphtheria carriers, as they may be called.

Certain practises in schools conduce to the spread of the bacilli from the throats of the apparently immune to those who are susceptible. Among others may be mentioned the use of slates or lead pencils from a common stock, which necessitates the interchange of these articles from day to day. The common drinking-cup is also a frequent disseminator of the disease. Müller[1] investigated the throats of 92 children in the Charité Hospital at Berlin. The Klebs-Loeffler bacillus was found present in 20 children having no changes in the throat. Six showed the presence of the germs upon entrance to the hospital, while 14 were infected after admission. The spread of the bacilli from bed to bed could readily be observed. One patient had virulent bacilli in the throat for two and one-half months. Animal experimentation proved the virulence of the bacteria in twelve cases. Aaser[2] found that disinfection of a barracks occupied by a diphtheria patient and sterilization of clothing by steam at 110° C. did not check the spread of the disease. An investigation of the throats of the 89 men in the barracks, with the discovery that 17 contained virulent Loeffler bacilli, furnished a clue to the progress of the disease. These 17 suspects were isolated. One developed classical diphtheria, 2 lacunar angina, others remained well, except for a reddened condition of the fauces which persisted as long as the bacilli were found.

The experiences of the authorities just cited, as also of others, lead them to the belief that all persons who harbor Klebs-Loeffler bacilli in their fauces should be isolated. In one healthy child no method of treatment proved sufficiently potent to remove the bacilli from the throat, whereupon the isolation continued nine months.

[1] *Berliner Klin. Woch.*, November 8, 1897.

[1] "Yahrbuch f. Kinderheilkunde," Bd. xliii, Heft 1.
[2] *Deutsch. Med. Woch.*, No. 22, 1895.

The solution of this moot question would seem to be in the discovery of some treatment which would be effective in the elimination of this fatal disease producer. Until such knowledge is at hand there can be no doubt that our duty as practitioners is to isolate persons with Klebs-Loeffler bacilli when such a procedure is practicable.

The proof that diphtheria is at times communicated to susceptible persons by those in whose throats Loeffler bacilli are present led me to an investigation of the throats of a number of general practitioners as to the presence of the Klebs-Loeffler bacillus The appended table, embodying the results of these experiments, shows that of a total of 11 throats of healthy physicians examined, 2 showed virulent Klebs-Loeffler bacilli, two yielded pseudo-diphtheria bacilli, and 7 gave no significant growth:

Doctor.	Cases of Diphtheria or Tonsillitis in Practice at Time of Examination.	Result of Examination of Throat.
1.	No cases for three weeks.	No Klebs-Loeffler bacilli.
2.	Two cases of pharyngitis.	Pseudo-diphtheria bacilli.
3.	Two cases of tonsillitis.	No Klebs-Loeffler bacilli.
4.	Dismissed a case of diphtheria ten days before.	Klebs-Loeffler bacilli in pure culture. Luxuriant growth. Guinea-pig inoculated with culture showed a grayish membrane, necrosis and edema.
5.	One case of diphtheria.	Klebs-Loeffler bacilli present showing a slight growth. The bipolar stain well marked.
6.	Two cases of sore throat.	No growth.
7.	Several cases of pharyngitis.	Showed a streptothrix.
8.	No cases of throat disease for several weeks.	Sarcina.
9.	No cases recently.	No growth.
10.	One case of syphilitic sore throat; one case of tonsillitis.	Staphylococcus pyogenes aureus.
11.	No cases for several weeks.	Pseudo-diphtheria bacilli present.

It will be noted that the physician represented by Case IV. had ten days previously dismissed as cured a patient who had been sick with diphtheria and this same physician had in his throat Loeffler bacilli. The bacilli took the bipolar stain and seemed quite typical, but in order that their virulence should be established a guinea-pig was inoculated subcutaneously. The animal developed an area of necrosis about the seat of the injection. The necropsy showed the formation of a grayish membrane; in fact, the tissues surrounding the part were extensively edematous, and the internal organs were markedly congested. Typical bacilli were found at and near the seat of inoculation.

The subject of Case V. was treating a patient with diphtheria at the time his throat was swabbed. The typical Loeffler germs were found in rather scanty growth after twenty-four hours. The bipolar stain was easily produced in these cells; the bacilli were of the long and slender variety, hence did not bear a resemblance to the pseudo-bacillus. In mingling the culture with water, the material did not, as is true with the pseudo-bacillus, mix readily, but showed persistent little granules. This was probably the true bacillus capable of inducing the disease when in a favorable throat.

The result of this work is not without interest, in that there is in it unquestionably a partial explanation of the spread of diphtheria. The work of Flügge has shown that the minute droplets of saliva produced in conversation and thrown out in the act of phonation carry with them any bacteria which may be present in the throat. There is sufficient ground to conclude that physicians in this manner become unconscious aids in disseminating the disease.

In the light of the foregoing statements, there are certain precautions which should be observed in an effort to restrict diphtheria: First, the bacteriologic examination of every patient with a sore throat, not only for the sake of the patient, but also in the interest of others, who, when infected, may have a more serious form of the disease. Second, the isolation, when practicable, and an attempt at the removal of diphtheria bacilli in every case of convalescents and others harboring the germs in their throats. Third, a watchful care should be exercised by physicians to avoid contamination from diphtheria patients, and efforts should be made to free their throats of germs when present.

SUGGESTIONS CONCERNING EARLY DIAGNOSIS IN PULMONARY TUBERCULOSIS.[1]

By S. G. BONNEY, M.D.,
OF DENVER, COL.;
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF DENVER; VISITING PHYSICIAN TO ST. LUKE'S AND THE ARAPAHOE COUNTY HOSPITALS.

FEW subjects in recent years have attracted greater interest in the profession than the general problem of pulmonary tuberculosis. With a view to the ultimate lessening of the disease, medical attention has been directed to the advocacy of its prevention, restriction, and control through governmental authority and provision. More exact knowledge concerning its contagiousness has been promulgated among the laity by the dissemination of educational literature. Concerning certain special methods of treatment much has been written by enthusiastic, and occasionally conscientious, observers. Greater recognition is being given to the general conservative measures of management, the adaptability of

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

various climates to the different stages of the disease, and a greater appreciation accorded the beneficent influence in the community of carefully conducted sanatoria. Yet the unfortunate fact remains that thousands of lives are being sacrificed annually on account of mistaken or delayed diagnosis. It is now generally accepted that consumption is a curable disease, in the sense of its permanent arrest; that the earlier the diagnosis, the better the prognosis; and that only in early cases are genuinely satisfactory results obtained. The time is coming when the profession will not accept the somewhat vague reports of observers concerning various degrees of improvement secured from climatic change, serum-therapy, or general management. Rather will it demand more definite statements as to permanent results, with special reference to total arrest, shown by the well-substantiated absence of rational symptoms and physical signs. Such will be the basis in the increasing multiplicity of reports upon which authentic conclusions will eventually be based. Recorded results of such a satisfactory nature will never be rendered save in those cases in which the diagnosis is made early and the cases come under trained observation in their incipiency. Generally speaking, it has not been such a class of cases that I have been privileged to observe in Colorado, where the advanced case is the rule and not the exception.

Early diagnosis, then, assumes a position in the general consideration of pulmonary tuberculosis of vastly more practical importance than climatic change, general management, or prophylaxis. It is true that perfect accuracy of diagnosis may be established by the recognition of the tubercle bacillus, but not always before the destructive process has already considerably advanced, the constitutional disturbance pronounced, or even the development of secondary infection. I have not infrequently failed for a considerable period to discover the bacilli in the sputum in cases in which the physical signs furnished indubitable evidence of a recent and not inactive tuberculosis. In other cases the significance of the symptoms and signs has been incontrovertible before the appearance of expectoration. Due recognition is given to the diagnostic value of the tuberculin reaction. Recent investigations with the Röentgen-rays disclose their utility for diagnostic purposes in thoracic disease. Neither of these, however, by reason of the necessary restrictions upon their employment are ordinarily within the immediate reach of the general practitioner. The claim has been made for the diagnosis of the so-called pre-tubercular state from the morphology of the blood, but it has thus far lacked satisfactory confirmation. In view of the frequent obvious difficulties for the clinician in establishing an exact and early diagnosis through the agency of the microscope, the Röntgen-rays, and the tuberculin of Koch, is it not profitable at this time to review the well-known and perhaps old-fashioned principles of diagnosis with the aid of the stethoscope and thermometer, the careful and painstaking application of which are too frequently overlooked? The distressing results of error and delay have not been occasioned by inability to apply the newer diagnostic principles, but on account of the failure to adequately appreciate the significance of rational symptoms, to recognize accurately the physical signs, and to properly interpret their import. In the majority of instances the available data for diagnosis has been amply sufficient to warrant its provisional establishment and demand for suitable advice as to the mode of life and residence long before the medical attendant has awakened to a realization of his responsibility.

As illustrative of this I will refer briefly to observations made from my own experience. In reviewing my recorded cases of pulmonary tuberculosis I have selected therefrom a series of 546 seen in private practice and continued under observation for a considerable period in Colorado, although the disease was contracted elsewhere. Three hundred and eighty-eight, or 71 per cent., of the subjects arrived in the State with distinct evidences of tubercular infection in each lung. With reference to the duration of the disease before arrival, my statistics, computed from a conscientious inquiry concerning the time of onset of definite symptoms characteristic of the disease, are as follows: Less than 3 months thereafter, 36; 3 to 6 months, 65; 6 to 9 months, 67; 9 to 12 months, 70; 12 to 18 months, 83; more than 18 months, 225; total, 546. The total average period of delay in 546 cases is a little more than 18 months, affording abundant opportunity for advanced pulmonary and constitutional impairment. The average loss of weight from the normal at time of arrival is 19 pounds. Sixty-four and one half per cent. of the patients presented marked constitutional disturbance, as evidenced by a considerable rise of temperature, feeble and rapid pulse, distressing cough with abundant expectoration, impaired appetite, and a correspondingly greater loss of weight. Nearly 62 per cent. of this class did not seek climatic change until after one year had elapsed following the development of the disease, and 80 per cent. until after 6 months. One hundred and five, or 19.2 per cent., had well-defined cavities, nearly all of these exhibiting pronounced rational symptoms of constitutional disturbance, with rather more than the average loss of weight and an average duration before arrival of 20½ months. Two hundred and

seventy, or 47.6 per cent., presented a family history of strong inherited susceptibility to tuberculosis.

Concerning the method of onset, 83, or 15.2 per cent., upon careful investigation may be safely considered to trace the origin of the disease to a distinct attack of influenza. The average duration of the disease in this class before arrival was a little more than 12 months, much shorter than the period for the total number, while the average loss of weight was 21.9 pounds. It is perhaps interesting to note, somewhat irrelevantly, that the number of such cases has materially diminished during the past few years, the proportion in the first 200 cases—from 1892 to 1895, inclusive—being 19 per cent.; during 1896 and 1897, 18 per cent.; and for the 200 cases in 1898, being but little more than 9 per cent.

One hundred and twenty-nine patients, or more than 21 per cent. stated the onset to be of a definite bronchitic character with an average duration of 15 months and 24 days following the inception of a severe cold. The average loss of weight was 17.1 pounds. One hundred and fifty-nine, or 29 per cent., described it to be of a gradual anemic onset with an average period before arrival of nearly 2 years. The loss of weight was 17 pounds. One hundred and fourteen, or 20.2 per cent., presented the history of a sudden hemorrhage as the first symptom distinctly referable to the disease. Of this class the average loss of weight was 17.6 pounds, and the average duration before arrival was 2 years, 3¼ months, much longer than the average of the total number. Exclusive of those with definitely hemorrhagic onset, 134 had suffered from one or more hemorrhages in the subsequent course of the disease before arrival. Sixty-one are unclassified with reference to the method of development, a very considerable number of these following measles, typhoid, and pleurisy. Singularly, an equal number, 61, are found to have experienced a distinct idiopathic pleurisy either preceding the apparent origin of the pulmonary process, occurring as an initial manifestation, or developing subsequently. In 14 of these an effusion had been recognized. The average period following the pleurisy before arrival was 36 months.

Is not the character of the cases sent to Colorado a striking commentary on the necessity of a more thorough appreciation of the principles capable of everyday application, upon which to base early diagnosis? One of the significant features of the analysis is the relatively shorter period before arrival, especially in those cases beginning with influenza, and to a less extent in those with bronchitic origin, as compared with the longer duration of those with anemic, and more particularly hemorrhagic onset. It would seem to be apparent from this, (1) that cases beginning with an acute attack of influenza pursue a more rapid course, according in general earlier diagnosis and demanding more prompt climatic change; (2) that the occurrence of a hemorrhage does not convey to the mind of the medical attendant, as would naturally be supposed, its full and startling import as a diagnostic feature.

It is not my purpose to attempt a wearisome recapitulation of the rational symptoms and physical signs of pulmonary tuberculosis so familiar to us all. I am impressed, however, from a constant and more or less intimate association with pulmonary invalids that there are a few factors of recognized importance which are frequently ignored by the busy practitioner.

As regards the rational signs, the non-appreciation of the significance of morning cough, even without expectoration, persistent daily rise of temperature, loss of weight, and other well-known evidences of constitutional impairment would indeed appear inexcusable. But how often do we find denial or absence of cough, periods of normal temperature, and even recent increase of weight in the presence of fairly definite physical signs in the same way that we may fail to detect satisfactory physical evidences of the disease, despite rather pronounced subjective symptoms? It is apparent that the presence or absence of no single rational sign can be safely accepted as a factor of paramount diagnostic value. The grouping of certain clinical manifestations, without other satisfactory cause, should lead to strong suspicions of a concealed focus of tuberculosis despite immediate absence of physical signs. It must be added, however, that in the majority of instances the signs are present and recognizable once a thorough examination of the chest is made.

As preliminary to a detailed consideration of the rational signs on the part of the medical adviser there should be instituted a careful inquiry as to the extent of inherited susceptibility, the history of the individual with reference to the previous existence of idiopathic pleurisy with or without effusion, an apparently trivial or remote pulmonary hemorrhage, the occurrence of grip, a succession of colds, a protracted convalescence from typhoid or malaria, the history of a slowly resolving pneumonia, a recent severe attack of whooping-cough or measles, and others of etiologic importance. The development of indefinite symptoms following a history of any of these conditions should be regarded with grave suspicion. The initial occurrence of hemorrhage without readily assignable cause should furnish even in the absence of all clinical manifestations or physical

signs a strong, suggestive indication of the existence of an already active though limited focus of tubercular infection. Further, a pulmonary hemorrhage supervening in the course of other rational symptoms without physical evidences, should afford convincing testimony concerning the actual nature of the existing pulmonary process. The occasional dry but persistent unexplained cough, even unassociated with other rational symptoms should offer at least a clear indication for continued medical observation and repeated examinations. While the absence of an elevation of temperature constitutes no argument for the exclusion of the diagnosis of a tubercular deposit, its presence under certain conditions is assuredly an element of exceeding value. The characteristics of temperature of more especial significance and which can only be appreciated by repeated use of the thermometer at two or three-hour intervals in suspected cases, during a period of several weeks, are its regularity and atypical course, an average for the day slightly above normal, its usual though not invariable rise in the evening, and absence of corresponding systemic disturbance.

The thorough and painstaking examination of the chest immediately upon the development of suspicious symptoms, and its frequent repetition, if necessary, will usually suffice through the detailed application of the principles of auscultation and percussion in establishing for clinical purposes a sufficiently early diagnosis. As a matter of fact, such an examination is seldom made until a provisional diagnosis has become apparent from the rational symptoms, and the consultant at once recognizes physical evidences of advanced infection. Is it not, then, of practical importance, prefatory to a consideration of the more recent aids to the recognition of consumption, to continue to emphasize a more strict and conscientious adherence to the principles of physical diagnosis, now ignored in so many instances? Apropos of this I would especially condemn:

1. Delay in instituting any physical examination whatever until long after the development of pronounced constitutional and pulmonary impairment.

2. Failure to examine upon the bare skin, the presence of clothing effectually preventing any approach to accurate results.

3. Neglect to examine the entire chest, the bases, interscapular spaces, and axillary regions being frequently overlooked.

I would deplore particularly the existence of:

1. Erroneous conceptions concerning the significance of the absence of percussion-dulness at the apices, an active process often being capable of recognition by auscultation considerably before the evidence of consolidation are apparent.

2. The non-recognition, in the absence of râles, of the various modifications in disease of the normal respiratory sounds.

3. Inaccurate interpretation of localized diminished intensity of auscultatory sounds, elevation of pitch, harshness of quality and prolongation of expiration.

I would severely criticize:

1. Failure to utilize cough preceding forced inspiration in eliciting the presence of slight moisture in the finer tubes.

2. The non-appreciation of the almost pathognomonic significance of a circumscribed bronchiolitis, even in the absence of dulness or other auscultatory signs.

SOME SURGICAL ASPECTS OF SYPHILIS.[1]

By FRANK HARTLEY, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE NEW YORK HOSPITAL.

(Concluded from page 397)

In the Joints.—It is a peculiar fact that though all other manifestations of syphilis are well studied the joint lesions seem to be much overlooked. The surgeon probably comes in contact with these cases more frequently than the syphilographer, and much of the advance in this work has been due to the surgeons. It is scarcely possible to think that the acute and multiple synovitis occurring during the primary eruption and with slight fever can be mistaken by any one for acute rheumatism, yet such has been the case. The acuteness of the onset, the multiplicity of the joint inflammation suggest an infectious disease, the exact course of which should be found if suspected. The joint inflammations following the exanthemata, the multiple epiphyseal osteomyelites, gonorrheæ and large intra-articular hematomata, are not infrequently thus confounded with syphilis and *vice versa*. The difficulty in ascribing the true cause is more frequently due to imperfect history on the part of the patient and neglect on the part of the surgeon than it is to an actual difficulty in finding the cause. A differential diagnosis between this type of syphilis and the gonorrheal can only be thought of in the rarer cases of gonorrheal synovitis which are multiple and have the character of the swollen synovitis and peri-articular edema. In the pure gonorrheal synovitis without a mixed infection the synovitis is not attended by formation of pus and an edema in the surrounding tissues does not exist. Large intra articular hematomata, owing to the absorption of the serum of the blood, give rise to fever and multiple joint inflammation, but other-

[1] Read at a Stated Meeting of the New York Academy of Medicine, held March 16, 1899, in a discussion on syphilis.

wise to no symptoms. So also in many of the exanthemata multiple lesions may occur within the joints which give no other symptoms than those of swelling, very slight edema, and some slight fever. The subacute or chronic serous synovites occurring during the later stages of the acquired variety are histologically at first serous synovites and later become papillary synovites with at times defects in the cartilages of the joints. They occur generally without injury, are more or less painful and the fluid in the joint is generally abundant. Anchylosis is not present, but fremitus is induced within the joint due to the papillary synovitis and the defects in the cartilage. This variety requires to be distinguished from the tubercular hydrops, monarticular arthritis deformans and monarticular chronic rheumatic arthritis. In the former cases the subacute course as compared with the chronic, the want of local symptoms in tuberculosis as against syphilitic joints, the presence of the fluid in syphilis, as against the variability of fluid in the hydrops of tuberculosis, and the history and a careful examination will always allow one to arrive at a distinct diagnosis. In the monarticular arthritis deformans injury to the joint is a most distinctive symptom. The injury produces a compression fracture of the heads of the bones, and is frequently seen in the ankle and knee from injury received by falling from great heights and landing upon the feet The deformities in the articular plates, the deformities in the joint itself, and the foreign bodies present are sufficient when they exist to class the case as one of monarticular arthritis deformans. In the monarticular rheumatic arthritis the want of hydrops and a tendency to anchylosis are characteristic symptoms. The main striking point, however, in all these cases is the rapid response to antisyphilitic treatment, while the disease itself withstands all other kinds of treatment. In an uncertain case this is the very best diagnostic means

The third variety is one in which a gumma situated beyond the synovial membrane in the tissues of the capsule by extension to the joint gives rise to a serous or papillary synovitis. If the gumma extends into the joint a gummatous synovitis or arthritis is induced. This variety is comparatively easy of diagnosis since the presence of the gumma, of the ulcers, or the scars from other adjacent gummata without other manifestations of syphilis being present are generally sufficient to lead one to the diagnosis of a secondary joint involvement.

The fourth variety of acquired syphilis is a gradual involvement of the joint, secondary to a periostitis, or an osteomyelitis, and running the same course as the preceding variety. Its diagnosis usually depends upon the diagnosis of the bone lesion.

It often happens in the acquired variety that the diagnosis is dependent upon the previous or present manifestations of the disease and the multiplicity of the joint lesion, but one may be obliged to work without any of these aids, other than the joint lesion. It is especially so in the hereditary variety of syphilis and too much importance cannot be given to it, owing to the imperfect results obtained in the treatment of tubercular joints in children, and to the fact that many syphilitic joints are considered tubercular. We should not increase this number by including the syphilitic joints and we should select from the other the syphilitic joint diseases, for no disease does better under appropriate treatment.

These are more common than is generally supposed, thirty-seven per cent. of children having keratitis in hereditary syphilis have joint disease; eighty-eight per cent. occur in the knee-joint, and fifty-nine per cent. of them are double, existing upon both sides. Histologically, we have in the first variety a primary serous synovitis with or without cartilage defects. In the second, third, and fourth varieties we have a serous papillary or a gummatous synovitis. In the second, due to a periarticular gummata; in the third to a periostitis and osteomyelitis; and in the fourth to an osteochondritis with or without perforation into the joint or separation of the epiphysis.

The first variety, the serosynovitis with or without cartilage defects, is generally double and in the knee joints. These subacute cases are quickly suspected even though no manifestation of syphilis is present. Such a case I remember in a child of four years of age, otherwise healthy, with a double gonitis, subacute in character and but slightly painful. There was some local heat, but no contracture in the joint nor redness over the joint. At the time of observation the disease had been present twenty-one days at the least. Inunction of mercury and internal administration of the iodid of potash brought about a successful result within two weeks. This case I knew to be syphilitic, for the mother had been treated in the hospital for the same disease, and it was present at the time of the presentation of the child, and she was examined and found to have a well-marked syphilitic gumma of the cheek.

When the latter three varieties occur in late childhood, they may be easily mistaken for white swelling when they have reached the gummatous period. In the earlier stages when the exudation into the joint is serous or the synovial membrane is papillary and a peri-articular gumma, a periostitis, an osteomyelitis or an osteochondritis is present the distinction even when the joint lesion is unilateral is much

easier. Bilateral involvement in the knee, elbow, and ankle joints are especially suspicious. These joints are, moreover, characterized by greater mobility and a more pronounced pain and swelling of the ends of the bones, than exist in tuberculosis. In comparison with the acute articular or the gonorrheal rheumatism syphilis shows a decided absence of pain in rest and a more pronounced swelling. It must not be forgotten that in hereditary syphilis pains exist within the joints without observable reaction (an arthralgia). These pains resemble growing pains, and are often so classed, or are considered rheumatic. No hereditary lesion exists and the cause is not explained.

Bones.—Both in the acquired and in the hereditary variety of syphilis, the bones are primarily affected and it is probable that we meet the hereditary varieties mostly between the ages of five and ten years; they may, however, occur as late as the twenty-eighth year.

It is not with the more frequent varieties of bone syphilis, *i.e.*, gummatous periostitis or osteomyelitis that the surgeon finds his difficulty, for here multiplicity of the lesions, the part of the bone involved and its mode of involvement are generally sufficient, even when other manifestations are not present, to distinguish the process as being syphilitic. It is, however, in the first place with the exostosis, the hyperostosis and the osteophytes, especially in the hereditary syphilis, that the surgeon has to do, since their pressure upon the muscles, nerves, and organs may lead to severe symptoms which, when the disease is distinctly understood, may be easily relieved

Particularly interesting are the three cases of exostosis occurring during the first week of extra-uterine life reported by Labré. The first case was one of asymmetrical exostoses upon the upper epiphyseal line of both femora. The autopsy showed syphilitic disease on the epiphyseal line. In the second case an exostosis existed upon the lower end of the humerus which disappeared under the use of blue ointment and iodid of potash. In the other case an exostosis upon the trochanter major suddenly disappeared with the disappearance of a periostitis of the ulna under blue ointment and the iodid of potash. Labré therefore concludes thas a certain number of exostoses are syphilitic, and the diagnosis depends upon the age of the child at which the exostosis of syphilis takes place, as well to the fact that the treatment under blue ointment and iodid is curative. Fournier has lately described a case of exostosis of hereditary syphilis causing a most painful contracture of the forearm, which exostosis was discovered by means of the Roentgen-rays and was cured under proper treatment. He also describes a case of acquired syphilis in a man of sixty years, whose primary lesion was obtained two and a half years previous and which was followed by severe amyotrophic joint affections: multiple exostoses upon the metatarsus, tibia, fibula, radius, and frontal bone. These exostoses diminished under proper treatment. Again, the hyperostoses of syphilis are responsible for deformities in the articulations adjoining the disease, and for this reason care should be taken to observe them. Such deformities as are seen particularly in the ankle joint, where from tibular hyperostoses pes valgus may result.

The rapidly developing gummata of the skull and long bones are not infrequently confounded with tuberculosis or sarcoma. In making such a distinction in the skull or in the long bones, it is to be remembered that the osteomyelitis of syphilis is usually gummatous, and that the periostitis is usually a sclerosing process, and that in the acquired disease the diaphysis is involved. In the hereditary and early acquired syphilis the epiphyses are involved. This holds good in the long bones, whereas in the flat bones the process is more frequently a gummatous than a sclerosing one. In the differentiation of these three almost similar processes syphilis of the bone is characterized by its painfulness and its exquisitely chronic course. In the acute osteomyelitis, we have the location in the bone, the acute beginning and the high fever, the intoxication and the early development of pus. In the sarcoma its location near the epiphysis, its more rapid growth, its early involvement of the skin and its larger mass. In tuberculosis the location in the bone, the slight pain and the very chronic course, its cold abscess, and the large sinuses resulting are characteristic.

We find many mistakes made in diagnosis and some in the removal of syphilitic gumma for neoplasms. Such a mistake has occurred to Langenbeck in the case of a man, twenty-five years of age, who denied all previous syphilis. He was sent to Langenbeck with a diagnosis of lipoma of the shoulder. The tumor developed after a blow five months previous to Langenbeck's seeing him. This tumor had increased with severe pain and existed on the posterior surface of the right scapula. It was a sharply defined tumor; it followed the movements of the scapula and was not attached to the skin. The surface of the tumor seemed lobular. The skin over the surface had an ulcer with undermined edges and a base formed of necrotic fascia. Suspecting that the tumor was not a sloughing lipoma, but syphilis under the appropriate treatment he effected a cure.

It is probable that the subject reported as being

operated upon by Carl Reyher of St. Petersburg, in Langenbeck's *Archives* of 1897, vol. xxxvii, had a gumma of the shoulder. He removed a tumor from the shoulder of a man, fifty-three years of age, the microscopic diagnosis of which was fibrosarcoma. Within three months a local return took place in the scar. On the elbow and shoulder and deltoid muscle old syphilitic scars were found The tumor involved both the acromial end of the scapula near the acromioclavicular joint and the clavicle. The humerus was not involved. The diagnosis was sarcoma and syphilis. The shoulder was removed, together with the arm, by Von Bergmann according to Berger's method. The patient recovered and returned to his work and after two-years' time died. The autopsy showed the existence of visceral syphilis, and it is very probable that the shoulder was removed for a gumma instead of a sarcoma.

Again, so eminent a surgeon as Kuster has removed a gumma of the sternum for a sarcoma, and the error was justifiable since the iodid of potash did not act so promptly as is usually the case.

Such a case I had myself at the New York Hospital some three years ago. The man was admitted having had a portion of the sternum removed for sarcoma involving the upper third of the sternum and the sternoclavicular articulations. The man was sent to the hospital with a diagnosis of a return of the sarcoma. Careful examination of his history as well as the character of the local disease in the sternum soon convinced one of the possibility of syphilis. Proper treatment cured.

With the rarer variety of syphilitic involvement of the spine consisting (1) in ex- or hyperostosis in the cervical, dorsal, and lumbar regions, which may induce pressure upon the cord or the nerves and give rise to symptoms; (2) in an osteomyelitis with necrosis, which is a very rare condition. As a rule this osteomyelitis of the spine is tubercular or both syphilitic and tubercular.

With the development of gummata in bone fractures may occur from very slight injuries. In the acquired varieties these fractures occur usually in the diaphyses, whereas in the hereditary variety they consist in the separation of the epiphysis trom the diaphysis induced by a gummatous osteochondritis in the first years of life and give rise to a condition known as Parrot's pseudo-paralysis.

In the Rectum.—Syphilis is frequently located and has been not infrequently removed under the head of cancer. Carcinoma, which exhibits an irregular, hard, and nodular growth with deep, gaping ulcerations upon the hard and indurated rectal wall, can be easily mistaken for chronic inflammation and ulcers, and these two for syphilitic stricture and ulcers or an anorectal syphiloma.

Rectal disease may be subjected to the microscope and if only small-celled infiltrations are present and granulation tissue, one naturally thinks of syphilis although the history and examination of the whole body reveals nothing. This negative diagnosis, however, is of little value unless we substantiate it by other general symptoms or by a characteristically diseased rectum.

Were we able to see the cases early diagnosis would often be an easy matter, but this is not the case and we cannot see the most characteristic manifestations in the rectum, *viz.*: the small gummata of the mucous membrane. It is characteristic of syphilis of the rectum to have the ring-like strictures close above the internal sphincter, above which, according to the age of the process, we find ulcerations, circular, with clearly cut indurated edges, not undermined, existing singly or occurring in groups, or we find above this stricture gummata globular, elastic, cellular deposits situated in the submucous tissue and existing singly or in multiple form. These gummata not infrequently undergo fatty degeneration and are replaced by a fibrous mass, which not infrequently when several exist is mistaken for carcinoma. Again, syphilis of the rectum may exist under the form of anorectal syphiloma of Fournier, which process as you are aware consists in a fibrous hyperplasia of the mucous membrane without ulcers unless it be secondary to it. This leads to a stricture which extends rarely higher than 2½ inches from the anus. Sooner or later either in the hereditary or in the acquired variety of syphilis the rectal wall above the stricture is studded with papillomata or adenomata. The microscope here may show nothing for or against syphilis even when it exists. Macroscopically above the stricture and the papillomata the ulcers and the gummata along the extreme edge of the advancing syphilis alone afford us the diagnostic evidence of syphilis. Microscopically the most evident lesions are obtained above the stricture and the ulcerated gummata. Here the mucous membrane is completely transformed into a granulation tissue composed in part of leucocytes and in part of epithelioid cells with large spaces between them (blood spaces without walls). In the submucous tissue gummata are found which consist of granulation tissue, perivascular and endovascular, similar to that found in angiosarcomata. So also in the gummata which present themselves as nodules, the formation from vessels is the same, so that in both cases the cells in the tissue stand in close relation to the walls of the vessels. Of the greatest diagnostic value, therefore, is the hard, bluish-red no-

dule in the mucous membrane which consists of this network of capillaries and small veins, the walls of which are in a state of proliferation producing epithelioid spindle and round cells. Following this disease in the mucous membrane the submucous and the intermuscular gummata appear, and owing to the necrobiosis of their tissue lead to the serpiginous ulceration when superficial, and when deep to strictures and contracture.

With reference to a distinction between syphilis and many other affections which simulate it, it appears to me to be useless to arrange in columns as in our text-books the striking differential points, for it is not where these differences can be recognized that our errors exist, but rather in the cases where this fails and where we are to judge largely from a few facts which render the diagnosis probable rather than certain. In this category of suspected and doubtful cases are placed those in whom (either child or adult) the manifestations of a recent or remote infection exist (acquired), or the evidence of a family taint is well founded (hereditary). Equally suspicious are the so-called tumors of muscle, since syphiloma of muscle is more frequently met than other tumors in this tissue. In Esmarch's experience it amounted to more than one-half of all primary tumors in the muscular system. We must class as doubtful all cases appearing to be sarcomata, recurring rapidly after removal (Paget's rapidly recurring fibroids). Many of the cases so classed have been proven to be syphilitic and have been cured by antisyphilitic treatment, although the pathologic examination has been that of a angiofibroma. Just such a case came under my observation in 1898. The patient was sent to me by Dr. J. P. McGowan of this city for the correction of a deformity in the upper lip the result of contracture during the dissipation of a gumma by internal treatment. The gumma had been an extensive one, and the connective tissue remaining had formed a mass the size of the thumb. The skin over the mass was not involved. It was adherent to the superior maxilla, and was to the touch hard and easily circumscribed. It had remained in this condition for two months, and at the time seemed to be stationary. This mass was removed, the deformity was corrected by a slight plastic operation, and the patient kept under internal medication. Pathologic diagnosis: Fibrosarcoma. This diagnosis could not be believed in since the evidence of former syphilis was present, nor have we up to the present time any reason for changing our diagnosis of a fibroid degeneration of a syphiloma of the muscles of the lip.

Another class of suspicious cases are those which have been cured by erysipelas; in both lupus and the severe syphilides the toxins of erysipelas apparently act antagonistically and render nil their respective toxins. It is indeed probable that the cures obtained in the treatment of sarcomata by the injection of the toxins of the erysipelas streptococcus and the bacillus prodigiosus may be explained in this manner. Such conditions existing in a case can only be considered suspicious, yet such a suspicion should be noted and acted upon since in not a few syphilitics a careful examination made to substantiate the diagnosis is fruitless. There are no characteristically colored scars. No exanthemata, no ulcerating syphilides, no gummatous swellings, thickening in the bones, nor can there be discovered the remains of an iritis. One is left with scarcely anything but the suspicion, and it must be acted upon with the idea of proving the case by histological examination and the antisyphilitic treatment.

In the syphilomata the method of growth has but little diagnostic value. Some grow rapidly, especially where they have been injured, which fact has been repeatedly observed by surgeons who have operated to correct deformities resulting from syphilis, while a latent but active syphilis was still present. Others grow more slowly until they break down and give the characteristic ulcer. Nor has the consistence of the syphilomata much diagnostic value since they may be either hard or soft owing to the amount of cellular constituents as compared with the purely fibrous. Some, moreover, when made up of a single gumma are smooth to the touch, while those consisting of an aggregation of smaller gumma are nodular.

Our anatomic diagnosis is then in many cases a most difficult one, and in some is impossible. Our microscopical diagnosis should be based upon a growth showing a grayish-red granulation tissue with several yellowish foci of fatty degeneration. Our microscopical diagnosis cannot always be relied upon, for although one may find a granulation tissue with foci of fatty cells, and an obliterating endarteritis or a granulation tissue with many vascular spaces and a peri- and endovascular proliferation of cells, yet it will often be impossible to say without a history of treatment—that it is not a fibro- or angiosarcoma. In the more or less diffuse infiltrations or in the fibroid degeneration where the interspersed gummata of the first or the fibroid masses of the second break down and result in ulcers with indurated borders and sloughy and fungous bases, it is difficult to decide macroscopically as to their cancerous or syphilitic nature with positiveness. Even with the microscope many sections must be examined in order to eliminate this same uncertainty. So

great is this danger and so easily have mistakes been made that Hutchinson, Brandes, Esmarch, Langenbeck, and others have given full accounts of their mistakes as a warning and an aid to others. In the cases presented to the surgeon the manifestations of syphilis play a most important rôle, and the closest scrutiny should be constantly exercised in order that it may be recognized at the earliest moment, and an immediate and appropriate medicinal treatment be instituted. It is only in this way that operative measures can be avoided or at least limited to their proper sphere.

Owing to the time allowed I have been obliged to omit any mention of the involvement of the sheaths of tendons or the bursæ.

CLINICAL MEMORANDA.

WOUND OF THE URINARY TRACT DURING AN OPERATION FOR ACUTE APPENDICITIS; SPONTANEOUS CLOSURE OF THE URINARY FISTULA; RECOVERY.[1]

BY CHARLES A. POWERS, M.D.,
OF DENVER, COL.

ON September 29, 1897, I was asked by Dr. A. A. Clough of Denver to see W. D., eighteen years of age, whose history, briefly, was as follow: Six months before he had had an acute attack of appendicitis which lasted three days. Local pain of a "grumbling" character, constipation and general indisposition followed. These had been fairly constant ever since.

The present attack began at noon on September 22d, with sharp pain in the umbilical region, vomiting, and fever. The bowels were freely moved by salines. On the following day, September 23d, his temperature was 104° F., his pulse 112, and the entire abdomen was tender and painful. The symptoms gradually subsided. On September 25th his temperature and pulse were normal, while the pain and local tenderness had almost completely disappeared. On September 27th the patient was out and about although he felt a bit ill. On the 28th the pain reappeared and he vomited profusely several times.

I saw him in consultation with Dr. Clough at 5 P.M. on September 29th, seven days after the onset of the attack. At this time his temperature was 101° F., and his pulse 100. There was moderate tenderness in the right iliac fossa on deep pressure. The abdomen was flat and not rigid. There was an elongated, rather tender mass the size of one's thumb at the outer border of the right rectus muscle below a line drawn between the anterior superior spine and the umbilicus. The bowels were well moved by repeated rectal injections. The following morning, September 30th, his temperature was 100° F., and pulse 108. The local tenderness had somewhat increased.

Operation was performed at St. Luke's Hospital at 11 A.M. with the assistance of Dr. Clough, Dr. J. M. Perkins and the members of the house staff. Ether was the anesthetic used. The ordinary incision was made at the outer border of the rectus muscle, and the general peritoneal cavity entered and carefully and thoroughly walled off. The cecum was recognized with some difficulty. The tumor felt through the abdominal wall was a hard mass of inflamed omentum and small intestine densely bound together by old, firm adhesions. In the depths of this the appendix was afterward found. With some difficulty the base of the cecum was turned up and the end of an enlarged and inflamed appendix discovered. This was slowly traced through old, dense adhesions downward into the pelvis. The small intestines were bound together in a mass by firm adhesions, and it was with great difficulty that the finger found its way along the appendix downward into the pelvis where it could be hooked around the tip of the appendix, and the latter liberated and worked up into a free position. As the finger brought it up out of the pelvis, between the adherent loops of the small intestines, a gush of straw-colored fluid (two ounces or more in amount) followed, and the same fluid welled up throughout the operation. A small quantity of this fluid was collected and found to contain urea.

The general cavity was further protected and the appendix, which was four inches long, friable, and gangrenous at three points, was quickly excised. An attempt was made to locate the source of the urine through the opening between the small intestines through which it welled up, but this was not successful. As has been said, the adhesions binding the intestines were very firm and dense, and it was thought unwise to persist in the effort. A catheter introduced through the urethra drew off a moderate amount of urine which was not bloody. A measured amount of fluid injected into the bladder came back in practically the amount introduced.

The operation-wound was well packed and an incision made in the median line just above the pubes. Through this the bladder was hastily examined. No wound was found. It was not possible to examine the right ureter because of the densely adherent intestines. The median incision was closed, except at the lower angle, where a small strip of gauze was introduced behind the bladder. The operative field on the right side was well washed and a glass drain introduced into the pelvis through the opening through which the appendix had been withdrawn. Another glass drain was placed at the upper angle of the wound at the inner side of the cecum and the remainder of the wound thoroughly packed with three-per-cent. iodoform gauze. Time of operation 2½ hours.

The patient's condition at the close was fairly good. He was placed in bed on his right side with the head of the bed elevated about two feet. The first forty-eight hours were stormy. He was very restless and in much pain. There was a profuse discharge of urine through the wound. That passed by the urethra amounted to about twenty ounces daily. At no time was it bloody. After

[1] Read at a meeting of the American Surgical Association, at Chicago, Ill., May 31, and June 1 and 2, 1899.

the end of forty-eight hours the bowels had been well moved and the amount of urine coming through the wound began to diminish. On the fifth day the urinary fistula seemed to be closed. The tubes and gauze were gradually withdrawn and the patient made a complete recovery, the wound being firmly healed at the end of six weeks. He has since remained entirely well.

A thorough search through literature, in which I have had the kind assistance of Dr. Edward Preble of New York, fails to show record of a case similar to the foregoing, and I feel it but just to publish the account as a warning of what may happen under similar circumstances. It seems probable that the urinary wound was of the ureter. It is quite possible that the appendix was adherent to it and that opposite a gangrenous patch in the appendix contiguous ulceration of the ureter had taken place. The ureter was not torn entirely across or such prompt cessation of the urinary flow would not have occurred. I cannot reproach myself with undue haste or roughness in digging the appendix out, and I can but think it wise that prolonged search was not made for the urinary opening.

At last year's meeting of this Association both Keen and Fowler presented interesting histories of cases in which the appendix had become adherent to the bladder, perforation having taken place. I regret my inability to find further literature bearing on the subject.

SUGGESTION AS A MEANS OF PRODUCING SLEEP IN THE CASE OF A PATIENT SAID TO BE INSANE.

By J. M. F. GIBBONS, M.D.,
of Scranton, Pa.

On Saturday, August 5, 1899, I was asked to see Mrs. B., who was suffering from acute melancholia, and treatment for such was advised. When I called on the following Wednesday she had not slept for three nights, notwithstanding she had been given 40 grains of sulfonal during that time. On the previous night she had endeavored to secure laudanum, obviously for suicidal purposes, but her son, realizing the danger, reported this to his father, and the patient was watched much more closely until I saw her on Wednesday.

At that time the boy was sent for a 2-ounce mixture of burnt sugar, alcohol, and water in proportions to render the most artistic effect, and this was labeled "laudanum" and "poison," and profusely decorated with cross-bones, etc. Until his arrival my visit was devoted to interviewing the patient's family, from which I learned that it was beyond their power to induce her to lie down, that she paced the floor night and day, and that aside from the sulfonal no medicine had been administered successfully.

The boy returned and gave the bottle to his mother, and then busied himself about the room according to instructions in order to observe the results of the experiment. The patient took the bottle and sent the boy into an adjoining room. A few minutes later the lad returned to me with the empty bottle. When twenty minutes had passed I entered the parlor and found her rapidly walking back and forth, much like a caged animal, and every action as well as her general expression gave evidence of the guilt she felt. When carefully questioned she reluctantly admitted that her effort to obtain laudanum had been successful. Feigning alarm, I told her that a few drops of the drug had frequently put a person in a deep sleep from which he never awoke. Questioned again, she admitted she had taken the entire contents of the bottle. She was cautioned with a semblance of excitement that if she were to lie down even for a moment she would go to sleep and die, and that her only hope for life rested in keeping awake by walking up and down constantly, just as she was doing at that time. Desperate in her determination to end her life, she went to her room, almost as I turned my back, and was found there half an hour later enjoying the first sleep she had had for hours.

Later in the week I called Drs. Frey and Reedy in consultation, with the result that the patient was removed to the Hillside Hospital. Of course there were other evidences of insanity in addition to those related.

MEDICAL PROGRESS.

A New Form of Hip-rest.—Braatz (*Centralbl. für Chir.*, August 5, 1899) describes a new form of hip-rest which is both convenient for the surgeon and is built on correct anatomical principles, so that the pressure upon the sacrum shall be distributed in the best manner. Besides the usual foot-piece and vertical support, there is a flat top almost exactly the shape of the "wish-bone" of a chicken, the point of which attached to the vertical support is directed toward the feet of the patient. The two legs of the "Y" extend upward, one on either side of the sacrum, so that the weight of the body is supported by the thick gluteal muscles and not by the sacral bones. The author has used this form of hip-rest for a number of years, and has found it in every way satisfactory.

The Spread of Contagious Diseases in Children.—Vollmar (*Berliner Klin. Woch.*, August 21, 1899) has made an exhaustive study of the above-mentioned subject, and comes to the conclusion that schools are responsible in large measure for the spread of contagious disease. While admitting that this can never be entirely overcome, he still emphasizes the importance of more careful measures in order to limit the spread of contagion as far as possible. Such measures should be in the hands of special sanitary officers. Before a child is allowed to return to school, after recovery from a contagious disease, its person and all of its clothing should be thoroughly disinfected. The schoolrooms should be disinfected at least twice a year, and the floor of the classrooms and corridors should be disinfected every week. It is the duty of physicians and parents to see that the measures determined upon for the prevention of contagion are conscientiously carried out. Parents, teachers, and children ought to be informed of the ways by which contagious disease spreads, and of the most practical means of prevention. All schools should be regularly visited by physicians.

Total Extirpation of the Internal Saphenous Vein.—CASSITI (*Centralbl. für Chir.*, July 22, 1899) extirpates the internal saphenous vein from its termination in the crural to a point well below the knee. He has obtained excellent results in cases of varicose ulceration and varicose veins. In order to avoid making a very long incision in the skin, he proceeds as follows: An incision of 4 cm. (1½ inches) long is made over the vein about 8 cm. (3 inches) below the groin. The vein is isolated and divided between two clamps as high up as possible. It is freed as low down as possible, and if firmly drawn upon it may be divided and tied considerably below the point of incision. Another cut of equal length is made just above the knee, and through this in a similar manner the vein is liberated above and below and drawn out through the wound. Two similar incisions made below the knee suffice to complete the removal of the whole vein. It is not necessary to ligate its branches. By this method a bandage in the groin and a scar at the flexure of the knee are both avoided, and through incisions aggregating only 16 cm. (7 inches), 80 cm. (32 inches) of vein can be removed.

Resection of the Liver for Neoplasm.—KEEN (*Annals of Surgery*, September, 1899) has collected and analyzed reports of 76 cases of resection of the liver for hepatic growths. The termination in the case of 2 patients was uncertain; of the remaining 74, 63 recovered, giving an operative mortality of 14.9 per cent. Shock, hemorrhage, and exhaustion caused death in 8 instances; septicemia in 2, and pulmonary embolism in 1. Four-fifths of the patients were females. This great disproportion in the sexes is attributed to the tight clothing worn by women. Echinococcus and hydatid cysts were found in 20 instances; carcinoma in 17; syphiloma in 2; adenoma in 7; sarcoma in 5, and rarer forms of new growth in single instances. The writer advocates an early exploratory celiotomy in every case. Until this is done one has very imperfect means of judging of the feasibility of the operation. Hemorrhage may be easily controlled by the cautery heated to a dull red, or, if necessary, by a few catgut sutures and temporary gauze packing. The question of recurrence cannot be intelligently discussed until a greater number of patients have been operated upon and their subsequent histories have been followed for a considerable time.

Simultaneous Disease of the Appendix and of the Pelvic Organs.—DUEHRSSEN (*Archiv für Klin. Chir.*, vol. 59, p. 921) systematically investigated 320 cases in which vaginal and abdominal celiotomy was performed in order to observe the condition of the appendix. In ten of the patients examined the appendix was found to be diseased, and in nine instances it was resected. The conclusion seems warranted that one may expect to find a diseased appendix in about three per cent. of cases of pelvic trouble requiring operation. This complication occurs especially under two circumstances, *viz.*, in inflammatory and particularly in suppurative disease of the adnexa, and in those instances in which there is a thick, short, right broad ligament. In the former class of patients the inflammation of the adnexa has led to peritonitis and inflammation of the appendix. In the latter the disease has extended through the parametrium and the appendicular-ovarian ligament to the mesentery of the appendix. In these cases a median abdominal incision with the patient in Trendelenburg's position is the most suitable one, even though the trouble seems wholly upon the right side.

Care of the Insane in Farm-Dwellings.—BLUMER (*Amer. Jour. of Insanity*, July, 1899) mentions the advantages which follow the care of the insane in farm-dwellings, a plan which has been put into practical operation in connection with the Utica State Hospital for some years. *A priori* it was argued that farmers would be too proud to board insane patients, but this has not proven to be the case, and the demand for insane boarders is constantly greater than the supply. Accidents are less frequent among the boarded-out insane than among a like number of patients in closed asylums. The thousand and one familiar things constantly going on around patients in families constitute a far greater source of enjoyment than the scenic entertainments of asylums. Economically the plan is a success, as the cost of the patient's maintenance is somewhat less on the farm and the value of their labor is far greater. Considered as a method of treatment, the plan is equally meritorious. This is not a new idea. A colony at Gheel, Belgium, is so old that its origin is surrounded by superstition, while in Scotland insane patients have been systematically boarded out on farms for half a century. The wonder rather is that it has not been more widely adopted in the United States. At least one-fourth and perhaps one-third of insane patients are adapted to this style of life.

The Importance of Local Treatment of Cystitis in Women.—SHOBER (*Jour. of Med. and Science*, August, 1899) emphasizes very positively the opinion that some form of local treatment is indicated in almost all cases of cystitis occurring in women. Even in the first stages of acute cystitis if the symptoms do not yield to constitutional measures in a very few days local treatment should be resorted to. The bladder should be carefully washed out with any one of the mild antiseptic solutions or with normal salt solution. A simple apparatus for this purpose is a pint jar with a rubber tube leading from an opening at the bottom, and connected with a two-way cock. After the urine has been carefully drawn, 1 to 4 ounces of the solution are allowed to flow into the bladder and then to flow out again. This washing should be repeated until the water comes away perfectly clear. Such treatment should be given from one to three times a day, according to circumstances, while the patient is kept constantly in bed upon a diet of the blandest character, with large quantities of diluent drinks. In more chronic cases attempts should be made to remove the cause by the repair of lacerations, correction of misplacements, removal of diseased tubes, calculi, etc. If the disease is localized in one or more areas in the bladder the latter should be emptied and the patient placed in the knee-chest or elevated dorsal position. The introduction of the endoscope

will allow the bladder to distend with air, and under these circumstances its entire surface can be inspected. Spots of local inflammation can then be treated by applications of a solution of nitrate of silver of from 5 to 20 grains to the ounce. As a last resort the surgeon is justified in establishing a vesicovaginal fistula in order to give the bladder complete rest. The patient is allowed to be about wearing a large pad of absorbent material. After a few months the mucous membrane of the bladder will be restored to a healthy condition and the fistula may be closed.

Surgical Relief of Cancer of the Stomach.—Guinard (*Rev. de Therap., Med., Chir.*, August 1, 1899) thus formulates the contraindications for resection for gastric cancer: The general state of the patient; the presence of visceral metastases or of large lymphatic metastases; immobility of the tumor from adhesions or because of its extension to the duodenum or esophagus. The conditions of operative success are given as follows: The avoidance before operations of all measures which can weaken the patient. Among these the author includes gastric lavage and purgatives. During the operation it is essential that the chloroform be administered in a perfect manner; that only healthy tissues be sutured, and these without tension; that the sutures be continuous in a spiral manner, and that all hemorrhage, even the slightest, be avoided. Rapid methods of operating are, therefore, superior to slow ones. After the operation the patient should receive nourishment by the mouth on the second, if not on the first, day. The patients are already feeble, and ought to quickly take some form of nourishment. Soup, chopped meat, peptones, and wine are suggested as suitable food. If vomiting recurs, the stomach should be washed out, the patient being in the recumbent position. The mortality of operation for gastric carcinoma at the present time has been reduced to about ten per cent. In doubtful cases exploratory laparotomy ought always to be performed.

Rectal Irrigation in Gynecology.—Hyde (*Amer. Gyn. and Obst. Jour.*, August, 1899) mentions a number of cases in which the value of rectal irrigation was strikingly exemplified. Prolonged douching lessens the normal vaginal acidity, a disadvantage which is obviated by rectal irrigation. It is also of value as a substitute for vaginal douches in young girls, although there are instances in which the vaginal douche is necessary for purposes of cleanliness. In acute and chronic ovarian and tubal lesions, except possibly pyosalpinx, this therapeutic measure has proved very satisfactory. In a case of intestinal paralysis with sepsis after operation repeated enemas and the free use of cathartics proved of no avail, and recovery was regarded as doubtful. Six gallons of water at a temperature of 115° F. were injected into the rectum. The intestines responded slightly after the second gallon, and strongly during the remainder of the injection. Large quantities of gas were evacuated, the patient became restless, and the pulse and temperature fell. Recovery was prompt. The dull aching pain and distress in the pelvis and slight tympanites which occasion so much discomfort after some pelvic operations may usually be relieved by rectal irrigation. Intestinal colic may be relieved in the same way. This measure was also tried in chronic constipation, but the results were doubtful.

THERAPEUTIC NOTES.

Treatment of Leucorrhea by Lactic Acid.—Sneguirev (*Journ. de Med. de Paris*, July 30, 1899), finding that the normal reaction of the vaginal mucus is acid and contains lactic acid, concluded that this substance plays a natural antiseptic rôle and prevents the development of various pathogenic microbes which find their way into the vagina. Consequently he determined to employ solutions of lactic acid to neutralize infectious bacteria. He found that douches containing three per cent. of lactic acid very quickly overcame the bad odor of the discharge, changed its color, and dried up the leucorrhea. Applications of lactic acid, either pure or in solution, made to the cervix or within the cavity of the uterus, caused an abundant desquamation of the epithelium and led to a cure of endometritis or endocervicitis with ectropion.

Treatment of Hyperchlorhydria.—This disease is generally caused by too much mental work (Einhorn "Twentieth Century Practice," vol. viii), therefore the patient's daily life as regards the amount of work, bodily exercise, mental rest, and pleasure must be regulated. In each case one must individualize. Cold sponge-baths in the morning for ten minutes before breakfast and exercise without over-exertion during the day must be prescribed. As to diet, all substances that are likely to intensely excite the glands of the stomach, *e.g.*, acids and spirits, must be excluded. The food should be rich in albumen. Starchy substances should be diminished. Whisky and wines should be avoided. Three large and two small meals should be taken daily. The two smaller meals should consist of a glass of milk, with bread and butter, or like fare. The food must be thoroughly and slowly masticated. A rest of at least fifteen minutes should be taken after each meal. In the way of medication, alkalies are indicated. From 3 ss to 3 i of bicarbonate of soda should be given three times a day two hours after meals, with the addition of magnesia and rhubarb when there is constipation.

This treatment can be continued for very long periods without any ill effects whatever. When the nervous element is pronounced (sleeplessness, headaches, over-excitability, etc.), one may make use of the following:

℞	Strontii bromidi	3 iij
	Aq. menth. pip.	3 xv.

M. Sig. Teaspoonful three times daily in milk at meal-times. This may be taken for a week or two, then discontinued for a short time, and again taken.

The use of electricity may be necessary. The faradic current is applied directly to the inside of the stomach. If the pain is great galvanization must be substituted.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 30, 1899.

THE NEW DISPENSARY LAW.

ON October the first, New York's new law for the suppression of dispensary abuses will go into effect. This legal enactment was the result of a vast amount of labor on the part of a goodly number of medical men; the law itself was drawn up with great care and represents the combined wisdom of many suggestions obtained after serious and sometimes heated discussion, in which the friction of advocacy and antagonism sometimes threatened to entirely consume the general interest in the measure itself. The unpleasantness is a thing of the past, dead, and let us hope buried without prospect of exhumation. The law is now to be enforced, and this will demand quite as willing cooperation among physicians as did its passage.

The abuses of medical dispensaries by patients, and doctors and managers alike, have been and still are most patent. The remedy so far as reasonable foresight avails lies in the provisions of the law and its wise and efficient administration. The evils that have been allowed to creep into our present dispensary system and become inveterate will not disappear of themselves; the enforcement of the law, in so far as regards the treatment of the poor at dispensaries, especially at first, should be judiciously applied and kept carefully free from the slightest degree of offensiveness.

The conference of representatives from various medical bodies who met at the suggestion of the State Board of Charities late in July of this year to discuss the methods of enforcement of the law made the following very practical and conservative suggestions: Every patient should be asked to sign a card stating that he or she is unable to pay for medical treatment; on the back of that card should be printed the section of the law making it a misdemeanor to receive medical treatment under false pretenses. All applicants should be treated at their first visit, but all cases should be promptly investigated by a central bureau as to the ability of the applicant to pay. No employe of the National, State, or City Government is to be considered a fit subject for medical charity unless he be a laborer, and not then if he have no one dependent on him. These suggestions are eminently fitted as far as they go to accomplish the exclusion of those not deserving of charity. The method, too, would take out of the doctor's hands the odium of enforcement of the law in the clinic itself.

The efficacy of the law, so far as the protection of the dispensary against those who are competent to pay is concerned, rests entirely upon the genuineness of the investigation. There is danger that this may prove only perfunctory and utterly fail of its purpose. There have been complaints of just this nature during the last few months in England. In London an attempt has been made to regulate the dispensary evil by distributing the general hospital charity fund only to those dispensaries which investigate the pecuniary status of their patients, so that the money presumably given to charity may not be diverted into unworthy channels. The reported investigations have, however, in some cases been evidently made with so little care that their object has been entirely defeated. The English medical journals have taken up the matter and a reform is demanded. We are liable to have just such a state of affairs develop unless the investigation is made a matter of serious moment from the very beginning.

THE ETIOLOGY OF YELLOW FEVER.

Considering the increased interest yellow fever has for us here in the United States since the acquirement of islands in the West Indies in which it has been endemic for a century, and from which most of the yellow fever that has at any time ravaged the American continent has come, we have been especially gratified to be able to present to our readers during the summer, the very latest details on the subject of its etiology from the best known original workers in the special department of bacteriology. Sanarelli, Sternberg, Wasdin and Geddings, Reed and Carroll, Novy, and Vitale are all men who have the right to be heard on the subject. How difficult the problem of the etiology of yellow fever is may be judged from the fact that at the end of the controversy the question cannot be said to be definitely settled.

Dr. Sternberg deprecates as preposterous the idea of a personal element in his non-acceptance of the specificity of Sanarelli's bacillus icteroides. His eminent attainments as a bacteriologist and his high personal character preclude the entertainment seriously of the idea by those who know him. Drs. Reed and Carroll have been able not only to impugn any aspersions on the accuracy of their laboratory work, but have made a distinct contribution to the subject of yellow fever and of intestinal affections generally in their review of the literature of acute fatty degeneration of the internal organs under the influence of various toxins, vegetable as well as bacterial. Of much more than passing interest is the fact brought out in their article that a number of bacteria that produce lesions of the intestinal tract in man and animals, the typhoid bacillus, bacillus choleræ suis and bacillus icteroides, bear certain striking relations to one another and to that normal inhabitant of the intestines the bacillus coli communis. This is not new but it becomes even more striking than before. The question of the possible polymorphism of bacilli, their existence under several forms with distinct properties in each, is becoming more insistent. It is clear that the further discussion of the etiology of yellow fever will be of value if for no other reason than the light it may throw upon this important problem.

Dr. Novy succeeds in maintaining his position that the failure of the bacillus icteroides to perish under the influence of cold certainly stamps with suspicion its etiological relations to yellow fever. Cold does not affect most micro-organisms but it does destroy at least one, the gonococcus, and medical history of epidemics seems at least not to disprove that the microbic cause of yellow fever is affected in the same manner.

The recent confirmation of Sanarelli's claims by the Marine Hospital workers in Cuba comes in the midst of the discussion and greatly adds to the probability of the etiological relation of the bacillus icteroids to yellow fever. Even yet, however, the question seems an open one. It is probable that we will have the opportunity to present to our readers before long a further contribution from Professor Sanarelli himself in which the recent discussion will be summed up and the work done on the subject this summer reviewed. With the present danger from the disease and the opportunities for study that the present epidemic affords we can only hope that interest will be aroused and the significance of points at present under discussion so thoroughly investigated that the important question will reach a definite issue before many months have passed.

PREDISPOSING CAUSES OF PULMONARY TUBERCULOSIS.

The medical profession generally has given up the idea, once so universal, that the development of pulmonary consumption, unless in exceptional cases, is connected with "catching cold." There is no doubt, however, that more cases of the disease come under observation in the fall than at any other time of the year. It is especially at this time, then, that hints as to the early diagnosis of the disease and as to conditions that predispose to it are of value. They serve the very beneficent purpose of anticipating the ravages of the disease before the condition becomes irreparable, and make very early treatment possible.

Two things worthy of note with regard to the predisposing causes have been prominently brought forward of late. Our London correspondent, in his letter published in the issue of August 26, 1899, called attention to the importance which was given at the recent meeting of the British Medical Association to Birch Hirschfield's work on the starting-point of pulmonary tuberculosis. The distinguished

Leipzig pathologist, one of the great German patriarchs in the science, found after careful investigation that in a large percentage of thirty cases of incipient tuberculosis in which the patients died from other causes the initial lesion of the disease was at one of the bifurcations of a particular bronchus supplying the posterior part of the apical lobe. He believes it to be a stagnation infection, and that the movement of air in this portion of the lung is not sufficient to remove bacilli should they prove to be in the air when originally inspired.

The prophylactic suggestion of the probable value of breathing exercises lies near at hand under these circumstances. It has often been noted that those most liable to consumption are shallow breathers, and the conviction has been growing that respiratory exercises for such people may be of the greatest service in warding off infection.

A second predisposing cause for pulmonary consumption is suggested by an article in the London *Lancet* for August 26, 1899. Dr. Byers reports a series of cases in which phthisis and Raynaud's disease were associated. There has always been more than a suspicion that individuals with a weakened peripheral circulation are more liable than others to pulmonary tuberculosis. The relations between skin diseases and lung troubles, as, for instance, asthma and psoriasis, have served to show that there is a close connection between the nerve- and blood-supply, probably between the vasomotor systems of the greater and lesser circulations. We have then in the disturbance of the peripheral circulation in Raynaud's and allied diseases the suggestion that the pulmonic circulation is similarly affected, and that a point of lowered resistance to the invasion of tubercle bacilli is thus offered especially at the periphery of the lesser circulation, as at the apices of the lungs.

The suggestion as to the connection between Raynaud's disease and phthisis is all the more important now that we know that the disease described by Raynaud is not a distinct entity, but only the severest stage of a series of circulatory troubles that may affect the ends of the limbs. Erythromelalgia, Weir Mitchell's disease, it is now about agreed, is a less advanced stage of the same disease, in which fingers and toes become only red and painful, not gangrenous. It is probable that very often the persistent tendency to cold hands and feet complained of by many people is a still milder form of the disease, but related to the severer ones and produced by like causes.

These considerations make obvious the necessity for careful inspection of the pulmonary condition of patients who come complaining of peripheral disturbances of circulation. Such care will undoubtedly sometimes lead to the detection of incipient tuberculosis at a time when it would not otherwise be suspected, at the most precious time as far as regards the success of treatment is concerned. These thoughts emphasize, too, the necessity for careful stimulation of the circulation in cases in which patients complain of circulatory troubles if the danger of infection with tuberculosis is to be avoided.

ECHOES AND NEWS.

Bacillus of Dysentery Discovered.—It was reported from Yokohoma, Japan, on September 18th that Dr. Kitasato has discovered the bacillus of dysentery and that he has already performed some remarkable cures by inoculation.

Death of Dr. Cusack.—Dr. Thomas G. Cusack died at Orange, New Jersey, on September 20th. He was graduated from the New York University Medical College in 1880 and was a member of the New Jersey Medical Society.

Successful Treatment for the Plague.—News comes from Paris on September 23d that the members of the French medical mission which was sent to Lisbon to investigate the bubonic plague announce that up to that date nobody inoculated with Yersin's antiplague serum had died.

Australasian Medical Congress.—The Intercolonial Medical Congress, composed of medical men from Australia and the neighboring islands in the South Seas that are under British dominion, or at least have English-speaking physicians, met at Brisbane from September 18th to 22d. The attendance was very large.

Compulsory Vaccination in Japan.—One of the latest signs of progress in Japan, and a very pertinent one it is, is the announcement that the Japanese government has decided to make vaccination compulsory in Japan, and that all children are to be vaccinated before they reach the age of ten months. They must be revaccinated when they are six and again when they are twelve years of age.

The First Automobile Ambulance.—It is announced that an automobile ambulance is being made for St. Vincent's Hospital, New York City. It will be propelled by electricity, and will be a model of its kind. Electric power, it is thought, will be more advantageous for propelling a vehicle for which it is essential to have a very steady mo-

tion. The large pneumatic tires will also contribute in no small degree to the comfort of the patients transferred by the vehicle.

Science and Diplomacy.—The visit of the French Science Association to Dover, England, which was noticed in the last issue of the MEDICAL NEWS, was returned on September 21st by Professor Michael Foster, President of the British Association, accompanied by the other officials and three hundred members. Boulogne was visited. The visitors were entertained at breakfast and in the afternoon were given a banquet in the Town Hall by the mayor and municipal officers.

Errata.—Through an error in the rendering of Dr. Vitale's manuscript into English for the last issue of the MEDICAL NEWS a portion of the second paragraph, first column, page 388, was made to read: "These observers noted in the case of three hogs . . . fed on *warm* cultures of bacillus icteroides." Instead of "warm" it should have read "bouillon." On page 389, second column, lines 17 and 18, the word "agar" should have been employed instead of "gelatin."

Inaugural Exercises at Jefferson Medical College.—On Monday evening, October 2d, Jefferson Medical College of Philadelphia will dedicate its new buildings and laboratories, which have just been completed and are ready for occupancy. Dr. Thomas Addis Emmet of New York, who is one of the oldest living graduates, having received his degree in the Class of 1850, will preside. The introductory address will be delivered by Dr. Phineas C. Conner of Cincinnati, O., who was graduated in the Class of 1861.

Antivenin for Snake-bites in India.—In view of the fact that the United States has a large body of soldiers now fighting in the Philippines where venomous serpents are not uncommon, a recent announcement from India is of more than passing interest. The British military authorities have become convinced of the value of Calmette's serum for the bites of poisonous snakes and have ordered the distribution of a supply of it to all the military hospitals in India. In certain parts of the French possessions in Africa it has been said to be most effective in preventing the evil results of snake-bite.

Treatment a la Brown-Sequard.—We learn from Joliet, Illinois, that I. F. Bush, a young man who had been pronounced insane and had been an inmate since last March of the Kankakee Insane Asylum, has been cured through treatment with lymph from the testicles of goats. It is Dr. Roberts, a Greene City, Missouri, physician, who is said to have discovered this lymph. Not to be behind Brown-Séquard, Dr. Roberts claims that his lymph will arrest senility. He has gone to Europe to lay the discovery before Professor Koch and others, with a view to having it used in European insane asylums.

Use of Saccharine Prohibited Abroad.—Germany has prohibited the use of saccharine for the production of beer, wine, etc. Other artificial sweetening substances are also interdicted. Belgium has prohibited the importation, manufacture or sale of saccharine except for medical purposes, and France also prohibits the use of these substances in food. In Great Britain saccharine must not be used in beer manufacture. In Spain, Portugal and Austro-Hungary similar laws are in force. As saccharine and similar substances are used very freely as adulterants in manufacturing in this country it is a little startling to note the general consensus of European countries in forbidding it.

Nomination of Officers of the New York County Medical Society.—At a stated meeting of the New York County Medical Society, held September 25th, the following were nominated as the officers of the Society for the following year: President, Dr. George B. Fowler; first vice-president, Dr. J. Clifton Edgar; second vice-president, Dr. C. N. Dowd; secretary, Dr. William E. Bullard; assistant-secretary, Dr. J. V. D. Young; treasurer, Dr. John P. Warren. Censors, Drs. Edward B. Bronson, Samuel O. Vander Poel, Henry C. Coe, H. Stearns, Eugene Fuller, Wendell C. Phillips. On the recommendation of the Comitia Minora nineteen new members were admitted to membership.

Officers of the Canadian Medical Association.—At its thirty-second annual meeting, held at Toronto, August 30 to September 1, 1899, this association elected the following officers for the ensuing year: President, R. W. Powell of Ottawa; vice president for Ontario, Dr. A. J. Johnson of Toronto; vice-president for Quebec, Dr. A. R. Marsallais of Montreal; vice-president for New Brunswick, Dr. Myers of Monckton; vice-president for Nova Scotia, Dr. W. G. Putnam of Yarmouth; vice-president for Prince Edward's Island, Dr. S. P. Jenkins of Charlottetown; vice-president for Manitoba, Dr. W. J. Neilson of Winnipeg; vice-president for Northwestern Territories, Dr. Hugh Bain of Prince Albert; vice-president for British Columbia, Dr. O. N. Jones of Victoria; treasurer, Dr. H. B. Small of Ottawa; general secretary, Dr. F. N. G. Star of Toronto. The next meeting of the association will be held at Ottawa.

Quarantine against Tuberculosis—It has been reported recently that Dr. D. D. Crowley introduced a resolution at a meeting of the California Board of Health, which was unanimously adopted, that it consider the propriety of quarantine against the entry of human beings or domestic animals suffering from tuberculosis. Quite a number of journals throughout the country evidently took this matter seriously, and bristled with editorials denouncing the idea. To us it seems hardly worthy of so much consideration. Almost daily, while Congress is in session, do we hear of bills being introduced into the House of Representatives, sometimes by the hundred, any one of which, if it could be considered a possibility to pass that body, would be sufficient to arouse the community to a frenzy of excitement These bills, however, are promptly shelved, the author subsides, and the country is saved. Let us hope that it will not require more than a second thought on the part of the originator of this resolution in California to convince him that it is the only wise policy to submit it to innocu-

ous desuetude. The comments that have been made are certainly sufficient to cause him to regret its conception.

The Yellow-Fever Situation while not alarming has developed certain features that make it appear more serious than when we went to press last week. Cases continue to occur from time to time in New Orleans. At the beginning of the week three new cases were reported in the city, and the Marine Hospital Service announced that it was carefully inspecting all trains that left the city for people who might already have any symptoms of the disease, or have been especially exposed. Toward the end of last week over twenty cases of yellow fever a day were being reported from Key West. On Tuesday of this week the newspapers announced the occurrence of twenty-six new cases. The Marine Hospital authorities have the place under good control, however, and no cases are being reported outside the town itself. There is not much excitement over the present condition of affairs despite the prevalence of the disease. The epidemic is a very mild one. While more than twenty new cases are reported as we go to press there has been but one additional death. The unfavorable feature of the situation is that Key West is below the frost line, and that as a consequence the coming of winter and colder weather will not put a stop to the disease which will have to be conquered by segregation and quarantine or must die out of itself when available susceptible material is exhausted.

The Future of Medical Congresses.— The *New York Medical Journal* calls attention editorially to the fact that the recent International Congress of Obstetricians and Gynecologists at Amsterdam has been made the text by one or two French journals of some spirited remarks concerning medical congresses in general. The feature that seems to have called forth these criticisms is the open-door policy of allowing everybody who chooses to attend and to take part in the proceedings. The original idea of the particular congress referred to was to restrict the papers and discussions to those who were invited by the managers to participate in the proceedings. The objection which the critics offer to this arrangement is that it would restrict the membership and attendance so greatly that the exchequer would be seriously embarrassed. The legitimate expenses attendant upon an assemblage of scientific men, gathered together for the purpose of discussing scientific subjects, however, need not be great. The extravagance that has gradually crept into such gatherings, in the way of elaborate dinners, luncheons, and excursions is entirely gratuitous; these superfluities are not necessary to attract the men whose opinions are desired, but are sought and enjoyed more especially by those who come under the head of "everybody who chooses to attend." The open-door policy is the correct one if the object is to get the profession together and have a good time, but if the chief motive is to secure a consensus of opinion of the leading lights of a specialty the side-shows should be eliminated and the membership restricted.

The Plague Situation has not improved and disquieting rumors are rife. The report last week that plague was in progress at Assuncion in Paraguay has not so far been officially confirmed. Some of the South-American ports have begun most rigorous quarantine to prevent the invasion of the disease. The United States of Columbia is reported as enforcing quarantine very strictly and Peru has followed her example. In Portugal the disease has not yet run its course and at least one new case has occurred since the 20th of the month. The sanitary cordon is accused of inefficiency, and there is very little sympathy among the people themselves with the sanitary measures. There is, however, a brighter side to the reports. A number of bacteriological and sanitary experts have arrived in Portugal from several countries to study and report upon the disease and the measures being adopted for its arrest. Dr. Shadwell, sent out specially from England, is stated to have reported favorably on the steps being taken by the Portuguese authorities to combat the epidemic. Although all agree that the epidemic is mild, increased virulence is dreaded when the next heavy rainfall occurs. The Portuguese government has availed itself of the several experts in Oporto to form an international commission to superintend the employment of antiplague vaccine. While in Portugal they fear that the colder weather may increase the virulence of the disease, in India, as will be seen later, they hope that cool weather will diminish its fatality and epidemic power. At Alexandria there is an interesting confirmation of the fact we noted last week, namely, that just when the sanitary authorities there think they have seen the last of the disease another case or several of them occur. The *British Medical Journal* announced September 16th, "We have the welcome news from Alexandria that at the present moment the city is free from plague; the last case left the hospital on September 7th. We congratulate the sanitary authorities in Alexandria on having got rid of the disease so speedily." On September 24th the daily papers announced the occurrence of two new cases of plague in Alexandria and one death from the disease. At Bombay about twenty new cases with two-thirds as many deaths are being reported daily. It is somehow hoped, though it is against previous experience, that the cold weather will reduce the incidence and the mortality from the disease. The following note from the *British Medical Journal* is practically an official announcement of the terrible situation that has developed with regard to the plague at Poona. "So virulent is the outbreak at Poona that the authorities of the India Office have advertised for medical men to proceed to India on a nine-months' engagement to treat plague. The salary will be 700 rupees, about $280, per month, but to those possessing the diploma of public health or who have already served on plague duty to the satisfaction of the authorities about $320 a month is offered. We understand it is not altogether the small pay that has caused the paucity of applicants for these posts, but the unsatisfactory positions assigned to civil medical men when they enter upon their duties. Applications have to be addressed to the Secretary, Revenue Department, India Office, Whitehall. The number of fresh cases and deaths in Poona amount to about 150 and 110 respectively per

diem. Three Europeans have been attacked by plague in Poona during the past week." In Russia there are certain cases of plague being officially reported, but a series of cases of an infectious disease of unknown character that is very fatal is being reported from various places along the Volga River. As this is a great waterway, and one of the most important commercial routes in the Russian Empire it is easy to see how important it is to know just what these cases are. It is more than suspected, in fact, it is openly suggested by sanitary experts in other countries, that these are cases of true plague. It is feared by many capable sanitarians that the invasion of Europe will come through the Ottoman Empire. The report of a case at Beirut, occurring in a traveler from Alexandria, has a certain adventitious interest for that reason. At Hong Kong there is a decided subsidence of the disease though it retains all its fatality. Most of the individuals attacked die. Along the China Coast generally there would seen to be at least a remission of the disease. Whether this is to be temporary or not remains to be seen, but remissions in plague virulence are quite common.

MEDICAL MATTERS IN NEW YORK.

DEATH FROM YELLOW FEVER—CREMATION IN CITY LIMITS—A BROKEN NECK MENDED—FORETOLD HIS OWN DEATH—A HOME FOR DEAF-MUTES—CITY CARE FOR TUBERCULOSIS PATIENTS—HEALTH REPORT.

PRIVATE OSWALD, who was taken to Swinburne Island from the transport "Buford" on her arrival from Cuba on September 18th, died of yellow fever on September 22d. The "Buford" was thoroughly disinfected, and was permitted to leave for Santiago on September 23d. The three yellow-fever convalescents who arrived from Key West on the "Lampasas" were released on September 25th.

The attempt of the Stephen Merritt Company to operate a crematory in the building at Nineteenth street and Eighth avenue has been frustrated by the Health Board at the instance of a number of indignant citizens in the neighborhood. The company officials declare it was their intention to cremate by liquid air, combined with electricity "and certain gases," and that the residents of the neighborhood would never be aware that a crematory were being operated. They hope to remove the opposition of the Health Board.

On September 18th, at Roosevelt Hospital, Dr. Robert Abbé performed an operation upon the cervical vertebræ of Walter E. Duryea, whose neck was broken on August 7th by a dive into shallow water. With Dr. Abbé were Drs. R. F. Weir and Arthur Fisk, surgeons, and Drs. Pearce Bailey and Fischer, neurologists. Mr. Duryea refused to take ether, and was conscious all through the operation, which was performed under cocain. By the X-ray it was found that the fifth cervical vertebra was fractured, and the posterior portions of the fifth and sixth vertebræ, which were pressing upon the spinal cord, were removed. The original damage to the cord was so great that a very guarded prognosis was made after the operation. At last accounts the patient had slightly improved.

Dr. Luke D. Broughton, homeopathist and astrologer, and for many years president of the Astrological Society of America, died on September 22d at his home at 68 South Washington Square. It is said that he combined the practice of astrology with that of medicine, and that he cast the horoscopes of all his patients. If by this process he would find that a patient who consulted him would die shortly he would do nothing to save him, acting quite in the spirit of the eminent jurist who has lately advocated the right of the individual to a natural death, without interference on the part of physicians with a view to prolonging life. Dr. Broughton is said to have cast his own horoscope and to have foretold his own death.

Up on Washington Heights, between Broadway and Boulevard Lafayette, there is a home called "Fanwood" in which deaf-mutes are sheltered and instructed. The institution began in 1818 at 41 Warren street, with four inmates. In 1829 it was removed to Fiftieth street and Madison avenue, and in 1853 the present site was occupied. Mr. Enoch Henry Currier, the principal, has been a devoted instructor of the deaf-mute for twenty-seven years past. The course of instruction is similar to that at academies in this State. Both boys and girls are taught cooking. A mechanical trade is taught to each boy. During the past eighty years 3729 afflicted children have been educated—hundreds of them free of charge. Among these there have been 7 college professors, 15 clergymen, 7 physicians, 3 lawyers of distinction, and 16 principals of schools for deaf-mutes, not to mention many men and women who in less conspicuous capacities have been useful citizens.

The State Board of Health met at Quarantine in New York Harbor on September 22d, and put itself formally on record as favoring the establishment by municipalities of institutions for the care of tuberculosis patients. Resolutions were adopted recommending to the Legislature that the New York authorities take steps to establish a hospital for consumptives outside of the city limits, and asking the support and cooperation of physicians in an effort to secure action to that end. The authority to establish such a hospital is given, by an act passed by the last Legislature, to any city of the first class, whenever its Board of Health shall deem it necessary for the promotion of the health of its inhabitants. The city Board of Health is to select the site and submit it to the State Board for approval. If thus approved it may be acquired by ordinary processes. It is also provided that wards for the treatment of pulmonary tuberculosis shall be set apart in existing hospitals, with separate nurses, cooking utensils, and washing facilities and plumbing. The city Board of Health, although it has not yet acted, will undoubtedly proceed in unanimity with the State Board. The question of quarantine against tuberculosis was not considered at this meeting. Dr. Daniel Lewis of New York, the president of the State Board, Drs. Doty of New York, F. W. Smith of Syracuse, S. C. Jones of Rochester, and State Engineer Bond were present. Dr. B. T. Smelzer acted as secretary. Reports were also received

in reference to vaccination and the successful prosecution of the work by Boards of Health in schools.

The Health Department submits the following report of contagious diseases for the week ending September 23, 1899: Measles, 55 cases and 7 deaths; diphtheria, 145 cases and 26 deaths; laryngeal diphtheria (croup), 5 cases and 6 deaths; scarlet fever, 80 cases and 4 deaths; chicken-pox, 4 cases; tuberculosis, 106 cases and 128 deaths; typhoid fever, 85 cases and 19 deaths; cerebro-spinal meningitis, 9 deaths; total, 480 cases and 199 deaths.

CORRESPONDENCE.

THE DIDACTIC LECTURE—A REPLY TO DR. HARE.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In reply to Dr. Hare's letter, published in your issue of September 23, 1899, I beg to say that Dr. Hare's opinion with regard to the didactic lecture seems to have changed somewhat in the interval between his two letters. He says now: "The point which I desire to emphasize is that the didactic lecture cannot be absolutely expunged from the roster of the medical school as some would have us believe, although of course such lectures should be much less numerous than they have been in years past." He said in his previous letter: "No means of teaching so well as the didactic lecture enables the student to benefit by the personal experiences of the teacher at whose feet he is studying." Perhaps when he wrote his former letter he wished to make it clear that he advocated the reduction of the number of didactic lectures given at our medical schools, which is of course all any one asks for the present, but if he did he was unfortunate in the expressions chosen to set forth his meaning. Take, for instance, the following sentence, which I quote partly because it seems to me to confirm the position I assumed Dr. Hare to hold in the matter and partly because it illustrates some of the involution of his manner of expression: "The popularity of lectures upon history, literature, art and travel, attests the fact that people enjoy and learn much by attending them, and in addition to imbibing statements of fact which fall from the tongue of the capable teacher, there is in the medical didactic lecture a possibility for the student to grasp the necessary details in connection with the lecturer's theme, which are so essential and so valuable in practical medicine."

Very truly yours,

JAS. J. WALSH.

1973 SEVENTH AVENUE,
NEW YORK, September 25, 1899.

For Fibroids of the Uterus.—The extract of the mammary gland of sheep will often be found very helpful in regulating menstrual symptoms, causing increased regularity, diminution in the flow and of the pain accompanying it, while the tumor or tumors gradually decrease in size. Two to 4 grains of the desiccated gland are given several times a day (up to 12 grains a day) over a period of two months. A depressing action on the heart is not o be anticipated.—*Shober.*

MEDICAL MATTERS IN PHILADELPHIA.

THE PROPOSED CITY WATER-SUPPLY—ANNIVERSARY OF THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA—THE SANITARY WORK OF WOMEN — THE QUESTION OF STREET PARADES AND THE DOCTORS—THE FREDERICK DOUGLASS MEMORIAL HOSPITAL—THE LAYING OF THE CORNER-STONE OF THE LUCIEN MOSS MEMORIAL HOME — DR. ROTHROCK REAPPOINTED STATE COMMISSIONER OF FORESTRY —APPOINTMENT OF ASSISTANT PATHOLOGISTS TO THE PHILADELPHIA HOSPITAL — HEALTH REPORT OF PHILADELPHIA.

PHILADELPHIA, September 25, 1899.

FINALLY, after seemingly endless discussion, postponements, and bickerings, the question of the filtration of Philadelphia's water-supply is on the high road toward solution. The commission of three experts, appointed by the Mayor to investigate the question, has just rendered a report covering the entire field, which report was immediately transmitted to Councils for their consideration, and will in turn be submitted to a popular vote of the people of this city at the November elections, if the present plans of the administration do not miscarry. Essentially, the commission's recommendations call for the establishment by the city of plants for the slow filtration of the water-supply derived from both rivers, the Delaware and the Schuylkill, the total cost of the scheme being approximately $12,000,000, which amount it is intended to provide by the passage of a special loan bill. It is believed that now at last the vexed problem of pure water and how to provide it, is solved—or will be solved before many weeks have passed.

The spring of next year will mark the fiftieth anniversary of the founding of the Woman's Medical College of Pennsylvania, and the alumnæ of the institution are anticipating and planning for a fitting celebration of this epoch in the history of the education of women in medicine. Elaborate jubilee exercises are being arranged for this occasion, an interesting feature of which will be the presentation, at the next annual commencement, of a portrait of the late Dr. Ann Preston, who was a member of the first graduating class, and the first Dean of the Faculty. The winter session of the Woman's Medical College was inaugurated September 27th, the introductory address being delivered by Dr. Emma E. Musson, Professor of Laryngology.

The little circle of women, who about one year ago banded themselves together for the purpose of aiding the municipal authorities in promoting public health, has decided that in order to extend their field of usefulness it is advisable to become incorporated. Application to the courts for a charter has, therefore, been made, and henceforth the association will be known as "The Woman's Sanitary League of Pennsylvania." Many of the members have enjoyed wide experience as workers in other sanitary associations, and the first meeting of this new society, to be held during the coming week, will, it is confidently expected, inaugurate an important and busy winter session, to be characterized by increased activity, and by a largely extended scope of the society's labors.

At the meeting of the Philadelphia County Medical

Society, held September 13th, a committee of five members was appointed to confer with the Mayor on the subject of street blockades during the progress of parades, and to arrange to overcome the difficulty experienced by many physicians when on professional calls in getting through the lines of march. It is believed means will be devised by which physicians in future will be given the opportunity to pass through the lines.

The trustees of the Frederick Douglass Memorial Hospital have issued an appeal for funds, to be used in the erection of a larger and more modern hospital building, the expense of the new structure being estimated at about $75,000. The Frederick Douglass Hospital was established four years ago by Dr. N. F. Mossell, the first colored graduate of the Medical School of the University of Pennsylvania, and has devoted its purposes especially to the training of colored women in the nursing profession. Owing to the limited facilities of the institution, last year but six student-nurses could be admitted, out of a total of fifty-eight applicants.

The corner-stone of the Lucien Moss Memorial Home, of the Jewish Hospital, was laid with appropriate ceremonies on September 22d. The new building is to be a part of the main hospital and its cost, including construction and endowment, will be in the neighborhood of $200,000. It will be ready for the reception of patients next spring.

Dr. J. T. Rothrock has been reappointed State Commissioner of Forestry by Governor Stone. Dr. Rothrock was originally appointed to the position by Governor Pattison eight years ago, and so valuable has been his services that he has held the same office through three successive administrations.

At the last meeting of the Board of Charities and Correction held this week, the appointments of Drs. W. B. Jamieson and T. W. Kirkbride, as assistant pathologists to the Philadelphia Hospital, were announced.

The number of deaths in Philadelphia during the week ending September 23d was 371, or an increase of 7 over those of last week, and a decrease of 5 from the corresponding week last year. The following returns of contagious diseases were made: Enteric fever, 76 new cases, 6 deaths; diphtheria, 67 new cases, 18 deaths; scarlet fever, 54 new cases, 3 deaths.

SOCIETY PROCEEDINGS.

THE INTERNATIONAL CONFERENCE FOR THE PREVENTION OF SYPHILIS AND VENEREAL DISEASE.

Held at Brussels, Belgium, September 4 to 8, 1899.

[From Our Special Correspondent.]

THIS meeting may be regarded as one of the most significant in which medical men have ever taken part, since it marks the first international official recognition of the dangers of venereal diseases to society at large. Not only was practically every civilized country represented among the delegates, but the leading parts in the Congress were assigned only to those legal experts and medical specialists whose places at the very head of their respective professions are undisputed. Most of the Continental governments were represented, either directly by the cabinet minister in whose jurisdiction such social questions are placed, or by a personal substitute with equal authority. The *raison d'être* of this Congress lies in the fact that while the advances in medicine and sanitation have enormously reduced the proportionate mortality of many maladies, and in numerous instances have practically stamped out others, yet syphilis and gonorrhea have spread unchecked to every portion of the inhabited earth and into all classes of society, until today they constitute a greater and more actual menace to the health of the people than even cancer and tuberculosis.

The efforts of the Conference were not undertaken in the interests of those who lead an immoral life, but rather on behalf of the tens of thousands of innocent victims who, either through accidental infection or through the sins of husband, father, or brother, are forced to take up one of the heaviest crosses known to man, and bear it silently, often to the grave. It is only within the last few years that investigators have shown us the prominent part which syphilis plays in the etiology of the severest and most hopeless diseases of the nervous system and brain, and that gonorrhea is often in reality a general systemic infection, capable of causing in women inflammatory conditions of the uterus, ovaries, and peritoneum for which no efficient remedial measure has yet been found, and in both sexes such grave conditions as meningitis and peri- and endocarditis.

Inasmuch as the main questions, "The Dangers of Syphilis to Society" and "The Dangers of Gonorrhea to Society" formed the most important subjects for discussion, and about which the remaining themes were grouped, so it devolved upon the two gentlemen selected to present these questions to assume charge of the larger share of the work of the Congress. These men stand so preeminently first as the highest authorities upon their respective branches that a word concerning their personalities may not be out of place.

M. LE PROFESSEUR HENRI FOURNIER, who spoke upon the menace of syphilis to society, is of all the men in the world the one best qualified to do so. As *chef de clinique* of the venereal division of the world-famous St. Louis Hospital in Paris his experience is enormous. His books, "Syphilis et l'Herédité," and "Syphilis et Mariage," as well as those from his facile pen dealing with the treatment of the disease, have long been regarded as classics; they have been translated into all of the modern languages.

PROFESSOR NEISSER, the discoverer of the gonococcus and originator of most of our modern methods of treating gonorrhea, is not only the highest authority upon this subject, but his brilliant research work in the domain of dermatology has won for him a place among the specialists in this branch second to none in the world. Though still comparatively young, Professor Neisser is the director of the newly erected Royal Dermatological Hospital at Breslau. He also enjoys the still greater honor

of being the founder of, and leader in, what is now known as the "Breslau School," the tenets of which aim to sweep away the empiricism which seems to cling so persistently to the pathology and therapeutics of skin and venereal diseases, and the placing of these subjects upon a rational, scientific basis.

Among the medical men who presented reports upon the other questions on the program, perhaps the best known is PROFESSOR DR. KAPOSI, whose text-book on skin diseases is probably the best in the German language. He is the physician in charge of the dermatological clinic of the Vienna General Hospital, the leading exponent of the ideas of his venerated master, Hebra, and the undisputed leader—one might say czar—of the Vienna specialists in diseases of the skin.

PROFESSOR DR. LESSER of Berlin University and the director of the cutaneous and venereal division of the Charité Hospital of that city probably numbers among his students more foreigners than any other instructor in the same subjects in Europe, and any one who has had the privilege of listening to his instructive lectures will not wonder at the reason for his popularity.

DR. BESNIER is *chef de clinique* of the dermatological part of the St. Louis Hospital, an exceedingly careful, thorough worker and clinician, the presiding officer at the meetings of several Parisian medical societies, and a splendid representative of French medical science.

PROFESSOR FINGER of the University of Vienna has written two excellent works upon venereal diseases, and is Austria's most progressive specialist in this branch of medicine. As a close and accurate student of the pathology of syphilitic and gonorrheal processes Professor Finger is known throughout the world.

PROFESSOR LASSAR owns the largest and best-appointed private clinic in Berlin, and is the editor of the *Dermatologische Zietschrift*, in which the results of his own work and that of his assistants are published.

PROFESSOR YADASSOHN of Berne has already published several interesting articles upon the subject of prostitution and its control by the State. He was for several years first assistant to Professor Neisser at Breslau, and is, like his celebrated teacher, an expert in pathological histology and bacteriology.

The delegates from England contain among their number several of the most distinguished medical authorities in the United Kingdom. DR. JONATHAN HUTCHINSON of London is undisputably the highest authority on syphilis and venereal diseases among English-speaking physicians, and in the estimation of all other nations is placed second only to his friend, M. Fournier. Dr. Hutchinson enjoys almost every honor which British medicine can give.

As a syphilologist DR. ALFRED COOPER has already won a high position for himself, and his ably written books on venereal disease are very widely read. DR. RADCLIFFE CROKER of London is not only a splendid representative of the British dermatological school and the ideal type of the English gentleman, but as a specialist and teacher of diseases of the skin he stands among the best in the world.

COLONEL RICHARDSON and MAJOR MACPHERSON are the official representatives of the English Army Medical Corps.

PROFESSOR SAUNDBY is president of the Council of the British Medical Association, and delegate of that Society at the conference.

DRS. DRYSDALE of London and BIRBECK-NEVINS o Liverpool, HENRY WILSON, M.P., and MISS LEPPINGTON of Warwickshire are the leading English members of the minority which opposes official recognition of prostitution.

America was represented by DR. LISTON MONTGOMERY of Chicago, delegate of the United States Government, American Medical Association, Chicago Medical Society, and Chicago Board of Health; DRS. LUSTGARTEN of New York, BLOOM and KASDIN of the United States Navy. Of these Dr. Montgomery alone took an active part in the proceedings.

The above list is far from complete, and many names, known wherever medicine is practised, must be omitted for lack of space. Before concluding these notes some mention must be made of the splendid representatives of Japan. This country sent to the Conference no less than five, who were certainly a credit to their native land. In their thorough comprehension of the questions discussed, their extraordinary command of the three languages used, and their highly finished manners they won immediate recognition.

The majority of the members of the Congress arrived during the Saturday and Sunday preceding the opening session, and on Sunday evening were brought together and handsomely entertained at the Hotel Ravenstein, where they were afforded a most welcome chance to become generally acquainted. On Monday evening the presiding officer, M. Lejeune, received the members at his beautiful residence. The evening of the following day was used by the Minister of Foreign Affairs, M. Favereau, and his charming wife, who gave a ball. The Mayor of Brussels and Councillors of the city threw open the famous Hotel de Ville on Wednesday from 9 to 12 P.M., and gave the participants in the Conference a chance to see the beautiful works of art which this wonderful and historic structure contains.

The banquet, given at the Grand Hotel, for the foreign members by those from Belgium and the Organization Committee, was a delightful and brilliant climax to the hearty, sincere, and most lavish hospitality which, from the beginning, had formed such a leading feature of the event, and contributed so greatly to general cooperation in the work.

But the delegates and members were, at the close of the final session, shown a still greater honor, as the King of Belgium, who had been following the proceedings from day to day with great interest, journeyed from his summer palace at Lacken in order to receive the participants at the royal residence from 3 to 5 P.M., and to thank them for their labors.

The organization of the meeting was simply superb. On every hand the members found their wishes anticipated and fulfilled, their requests attended to with cour-

teous alacrity and precision, and such kindly aid shown one and all that the confusion, which is almost an inevitable concomitant of all large gatherings, was entirely absent. Each detail was systematized so thoroughly that the business went through with beautiful smoothness. Indeed, the amount of care and intelligent forethought was such, that upon the spontaneous suggestion of a large number of members, a subscription list was quietly started and so well subscribed to, that on the following evening, at the beginning of the banquet at the Grand Hotel, an exqisitely executed bronze statue was presented to the secretary-general and leading spirit of the organization committee, DR. DUBOIS-HAVENITH, as a grateful tribute to his ceaseless and untiring labors, which did so much to make the Conference so successful.

The beautiful *salle de débats*, of the Palais des Academie, embellished with famous historical paintings, statuary, and busts, was tendered by the city for the use of the gathering, and the scene at the opening session, Monday morning, September 4th, was both brilliant and impressive. The gala uniforms of France, Germany, Austria, Russia, and Belgium, as well as the colored ribbons, medals, stars, and grand crosses of the chief European civil and military orders, were everywhere in evidence. In a few minutes the members had seated themselves. The Minister of Agriculture and Public Works, M. LE BARON LE BRUYN, M. LE DR. TROOZ, Minister of the Interior, and M. BULS, Mayor of Brussels welcomed the members of the Congress in most cordial speeches and expressed the heartiest sympathy with the objects of the meeting, together with the sincere hope that success might crown the efforts of the assemblage. Dr. Dubois-Havenith then announced the selection of the following presiding officers: President, M. le Senateur le Jeune, Minister of State; Dr. Dubois-Havenith, secretary-general; Dr. Bayet, secretary. He then declared the meeting open, and the work of the day was at once begun.

The first question: "Does Official Control of Prostitution Lessen the Spread of Venereal Disease?" occupied both the morning and afternoon sessions of Monday and the entire session of Tuesday. Speeches were limited to a quarter of an hour, and in the first half-dozen discourses it became evident that while the majority of the members regarded municipal supervision of some sort as our only means of combating this terrible scourge yet the minority composed of DRS. AUGAGNIER of Lyons, A. FIAUX of Paris, and DRS. DRYSDALE, and NEVINS, MR. WILSON, M.P., and MISS LEPPINGTON of the English delegation, made up in aggressiveness what they lacked in numbers, and in vigorous speeches denounced as wholly bad every form of legal measures. The English members based their arguments upon the workings of their "Contagious Diseases Acts," which were abolished in 1886. They claimed that not only did these laws fail to improve the sexual health of the people, but the large increase of venereal disease may be directly attributed to such legislation. Here several members arose to question the thoroughness of execution of these laws. Drs. Augagnier and Fiaux based their opposition upon the many obvious defects of the present Parisian prostitution regulations, and presented to the members many elaborate tables of figures which were supposed to show the futility of all governmental interference. These formidable weapons in the argument were soon rendered useless, however, by an extremely clever motion by DR. EHLERS of Copenhagen, who reminded the members of the many failings of even the most careful tables of statistics, and advised that all speakers should dispense as far as possible, with these. The suggestion met with immediate general approval, much to the disappointment of the minority. The English representatives of the opposition had covered many square yards of the walls with huge statistical charts, and had relied chiefly on these for the basis of their antagonism.

PROFESSOR FOURNIER of Paris spoke several times of the workings of the present regulations, and freely admitted their many shortcomings and incompleteness. He said that in spite of their many obvious defects, many of which could be remedied, these measures could not help doing a very great amount of good, for even though they enabled the segregation and compulsory treatment of only a half or a third of all syphilitic courtesans, yet this meant the isolation of so many centers of contagion. And inasmuch as each woman would otherwise infect from two to four men daily, as prophylactic measures the value of all such laws are beyond dispute.

PROFESSER NEISSER heartily endorsed all that his predecessor had said, and desired to express his entire confidence in the ability of suitable laws, properly executed, to diminish the amount of venereal disease. We succeed in preventing the spread of many contagious diseases by legal measures, and if those against the most dangerous of all foes of public health, venereal disease, were to be executed with an energy equal to that with which we fight some of the acute exanthematæ, our results would be equally satisfactory. These is no reason why gonorrhea and syphilis cannot be enormously decreased, and in course of time almost stamped out. It is all a question of energy, determination, and concerted international action.

PROFESSORS KAPOSI of Vienna and LASSAR of Berlin believed thoroughly in the efficacy of official control. It is our only means of controlling existing evils and preventing their continued increase. Those who would abolish such control assume an attitude of unproductive cynicism, and are unable to suggest other practical remedial measures. The evil increases daily; something must be done for the sake of the health of future generations. Instead of disparaging all efforts toward lessening the spread of this disease, we should use our time and energies toward the perfecting of all means which are to day at our command. This is the only manner in which we can succeed.

MISS LEPPINGTON of Warwickshire, England, presented several aspects of the question under discussion, but as her discourse touched upon the moral rather than scientific side she was called to order by the president and obliged to desist.

DR. BIRBECK-NEVINS of Liverpool read what was perhaps the most representative paper of the opponents of

official regulation, but, like those of his countrymen, his arguments were based wholly upon the rather doubtful workings of the English prostitution laws, and hence did not make much impression. Dr. Nevins, after relating the results of all English measures on behalf of the Army and Navy, quoted statistics published some years ago by Professor Fournier. The latter gentleman, however, in a few words exposed the false interpretation to which his figures had been put, and Dr. Nevins retired.

The discussion of the first question continued throughout the first three sessions without any general and unanimous conclusions having been reached.

On Wednesday morning, the third day, work upon the second and third questions was begun. The theme, "Is the Present Organization of Medical Surveillance Capable of Improvement?" brought out many interesting suggestions. PROFESSOR YADASSOHN of Berne who, owing to the illness of PROFESSOR FINGER of Vienna was the sole official reporter, is already well known for his previously published works upon this subject. He made the following proposals: More frequent and more thorough medical examinations; syphilitics should be under control and treatment for their own sakes as well as that of the State for at least three years; first in the hospital until the infectious stage has passed, and then in the polyclinic (out-patient department). State control certainly does, to a certain extent, protect debauchery. It should, therefore, be generally known that even the best supervision can by no means *guarantee* against venereal infection; microscopic examinations of gonococci in all cases of suspected gonorrhea, and more thorough and longer continued treatment of this disease. DR. FIAUX (France) once more presented endless statistics to prove the harm which official control causes.

DR. LE PILEUR spoke of the practical workings of various systems of control applying to houses of ill-fame and *maisons d'assignation*, and expressed the opinion that such supervision should be arranged not only to offer far less offence to the public morals, but surely and absolutely to prevent the spreading of venereal disease. Indeed, it is in the houses that regulation could be carried out to perfection.

DR. HOEFFEL of Alsace-Lorraine, though a decided believer in official control, showed that such measures had been thoroughly carried out in Alsace, but for some reason unknown had proven useless.

DR. BLASCHKO of Berlin, author of several works upon the subject, took a position in the discussion between the advocates of official supervision and those who would abolish it. As a result of his large practical experience as an official of the sanitary police in Berlin he thinks the present systems in vogue are inappropriate because they apply only to the older prostitutes, and not to the more active, more dangerous, but less known younger ones. He proposed that only those prostitutes who are known to have caused venereal infection or are guilty of gross indecency should be placed under surveillance. In these instances compulsory laws are absolutely necessary.

M. RETHAN MACARE, Chief Justice to the Queen of Holland, opposed control of bawdy houses, as he believed this would increase immorality.

DR. BLASCHKO again rose to say that treatment of venereal diseases should be largely voluntary. PROFESSOR LESSER of Berlin disagreed upon this point. He said that infected women do not feel inconvenienced or actually ill, and, therefore, would certainly not be likely to present themselves for treatment of their own accord, but would more probably go about spreading their disease. They should have adequate treatment forced upon them, as much for their own sake as for the sake of public hygiene.

PROFESSOR FOURNIER of Paris stood decidedly for regulation, especially of brothels, as the results of supervision are in this class especially promising, and could be made more so. To omit this would be casting away one of our strongest weapons. The state of the prostitutes themselves would be greatly bettered; they would be freed from their present slavery to the keepers of houses, and would always have a chance to reform. The stricter police surveillance would make such resorts less attractive to revellers and all classes of patrons. From a sanitary standpoint everybody admits the immense improvement which would result. Then why not adopt such control?

MADAME BIEBER-BOEHM of Berlin, President of the German Society for the Protection of Young Girls, read an extremely able and reasonable paper. She called upon physicians to make more use of their opportunities to give sound moral counsel to their youthful patients.

On the fourth day, September 7th, although work upon the fourth and fifth questions of the meeting was begun, the speeches differed but little in their ideas from those of the previous days. It became a hotly contested discussion for and against official recognition of prostitution, rather than of the details of the subject. Nor was this improper, since the definite endorsement of control of prostitution by the State would render all other remaining work a matter of detail, to be adapted to the conditions prevailing in each country and perfected by the results of practical experience. That a unanimous conclusion could be reached was hardly expected, even by the most sanguine of the gathering. So the results of the prolonged debate were far from disappointing, though they left the subject practically where it stood at the beginning. One could note the almost hourly increase of interest in the work, and many prominent men, whose presence had previously been chiefly of the perfunctory sort, toward the closing hours became impassioned speakers for the affirmative or negative side of the question. That from now on the subject will receive the closest attention, not only from the highest medical authorities, but from students of social science and the most influential of public men as well, can hardly be doubted. It is in arousing such genuine, widespread, and enthusiastic interest in the question of prostitution and prevention of venereal disease that the Conference achieved a far greater and higher aim than anything which could be represented in a few crystallized resolutions. Nevertheless, these were not wanting, for after HERR SCHMOLDER of Wesphalia, DRS. MIREUR of Marseilles, FIAUX,

PIERSON of Holland and several others of the abolitionist side had stated their views in fifteen-minute speeches, PROFESSOR FOURNIER arose and offered for endorsement by the Congress the following recommendation:

"The International Congress for the Prophylaxis of Syphilis and Venereal Diseases expresses the desire that the various governments use all powers with a view to suppressing absolutely prostitution amongst girls who are regarded according to civil law as minors." After one or two inquiries concerning the technicalities of translating this into English and German had been made, the recommendation—the authors of which are Professor Fournier and the Minister of State, Lejeune—was passed by a unanimous vote amid great applause.

The remaining time of the day's session was put to excellent use by M. GEORGES HONNORAT, Chief of the First Division of the Prefecture of Police, Paris, who explained the workings of the Parisian regulations regarding prostitutes and brothels. As a result of his wide experience he has become a firm believer in the efficacy of official control of such women.

On the fifth and last day, September 8th, the interest and enthusiasm, so noticeable on the previous day, reached its height, and together with the brilliant speeches of the leading men and the passing of important resolutions, combined to form a fitting close to the memorable gathering.

M. RETHAN MACARE, PROFESSOR WOLFF of Strasburg, PROFESSOR HOLST and DR. MORGENSTEIN of Christiania were among the first speakers. PROFESSOR NEISSER then arose, and in a short but forceful speech expressed his views. To one who looks at the subject fairly and practically there is not the slightest ground for cynicism concerning the results of intelligent treatment of syphilis and gonorrhea. As one of especial experience in the treatment of the latter disease he wished to express in the strongest possible terms his disapproval of those who are therapeutic nihilists as far as these maladies are concerned. The prompt and energetic treatment of gonorrhea in its first stage is in nearly all cases followed by a thorough cure. The disease in the female, if we can attack it before it has passed beyond the cervix, will yield as readily as in the man. This is one of the strongest grounds for advocating official control of prostitution. Such control, if left chiefly in the hands of police officials, certainly would in many ways be open to well-founded objection. It should, therefore, be almost wholly medical in character, with police always at hand to enforce obedience.

DR. JONATHAN HUTCHINSON of London then arose amid great general enthusiasm, and his only speech at the Congress will certainly become a classic upon the topic. Dr. Hutchinson said that after studying syphilis and its manifestations as he sees it in England, he has become an optimist regarding the influence which the disease exerts upon the Anglo-Saxon race. He recognizes the extreme gravity of the malady, particularly in the etiology of the most fearful and hopeless affections of the brain and spinal cord, but deplores to the utmost the sensationalism which has caused such an exaggerated fear of the disease. As regulation is an impossibility in England, we must perforce confine our efforts to suppressing as far as possible the transmission of the contagion. After an experience extending over fifty years, Dr. Hutchinson has reached the conclusion that when syphilis has existed in a patient for a period of two years it is then incapable of being transmitted hereditarily. The spread of the infection is thus, to a certain extent, limited by time. Hereditary syphilis is almost unknown in the better classes of society, and if the poor people—who suffer from it most—could enjoy the same facilities for treatment, they would be equally free from such forms of the disease. Syphilis which has been inherited does not extend to the third generation. Dr. Hutchinson heartily endorses early treatment, as when this is begun before the secondary symptoms appear, the most contagious period of the disease is entirely suppressed, and the danger of contagion accordingly diminished. This method is now so generally used in England that in private practice a well-marked case of secondary minifestations is comparatively rare. The hospitals should readily and willingly admit all cases of syphilis without question and give thorough treatment for the disease.

All places where young men congregate should be made to furnish instruction upon the dangers of prostitution and the venereal diseases. Moral education, without reference to religion, should endeavor to foster higher respect for women. This, now more prevalent than in former years, Dr. Hutchinson has noticed particularly among his medical students. The sense of responsibility in sexual matters should be increased. The Quakers believe in the laudable idea of masculine chastity until marriage, and to this the speaker attributed the total freedom of this sect from general paralysis of the insane. In regard to the Army and Navy, the old notion that drunkenness and debauchery is only to be expected of the common soldier and sailor should be done away with. We should make him respect himself, and in turn respect him as we do any decent workingman.

There should be better post-graduate medical education in order to enable all practitioners to receive the instruction and experience necessary for the accurate diagnosis and proper treatment of venereal disease. Under the systems of teaching now in vogue this, the right of every patient, could hardly be expected of the young medical graduate.

As a result of his individual knowledge of the extent of syphilis prevailing in the English Army, Dr. Hutchinson believes that the reports of its influence upon, and frequency among, the men has been greatly exaggerated, and the official reports upon the subject falsely interpreted. He is strongly opposed to the State taking under its protection such a vice as prostitution, but is sure that the people of Great Britain would gladly endorse all other means, which will probably be of a moral character.

PROFESSOR LESSER of Berlin did not agree with Dr. Blaschko regarding voluntary treatment of venereal disease. That is, that treatment of venereal disease should be made optional, not compulsory, in the out-patient department of hospitals, as the class who are seen here live

in dwellings which from a hygienic standpoint are miserable, and have neither means nor facilities for obtaining nourishing food and bathing which to-day play such an important part in our modern methods of treatment of severe venereal cases.

PROFESSOR FROISFONTAINE of Liege showed the Congress copies of the little books of advice and warning of the contagious nature of the maladies and necessity for their cooperation for thorough treatment, etc., which are supplied to the venereal patients of the Royal University Dermatological Hospital of Breslau. Professor Froisfontaine heartily endorses this simple but effective means of diffusing knowledge of the contagiousness of syphilis and gonorrhea among lower circles.

PROFESSOR FOURNIER of Paris suggested that the best prophylaxis against the spread of venereal disease is the more thorough treatment of that already existing. This is especially so regarding syphilis. If necessary the expenses for thorough treatment of each case should be borne by the government. It should supply ample free treatment for all specific cases applying for such. In each patient the cost to the government of all medicines would not be more than a dollar, and for this sum the treatment would in all cases certainly tide over the most infectious stage, and in many result in a permanent cure. The speaker, therefore, offered the following suggestions: (1) Absolutely free treatment for all cases of syphilis. (2) The facilities for the most thorough treatment of all cases of syphilis should be improved and extended. (3) The privacy of the consultation of a free venereal patient with the hospital physician should be equal to that prevailing in private practice, and measures ought to obtain this result. It should be made a rule that each patient's talk with the physician should be behind closed doors and alone with him. The methods now existing in many hospitals amount almost to a "public confession" of syphilitic infection. This not only injures the patient's social prospects, but his material ones as well.

The speaking at the Congress was now at an end, and the following recommendations, which had been carefully prepared by the members during the previous two days, were then unanimously adopted.

I. The resolution of PROFESSOR FOURNIER, as already stated, concerning international measures for the abolition of prostitution among females of minor age.

II. That the present conference serve as a beginning for the foundation of an International Society for Moral and Sanitary Prophylaxis against the Evils of Prostitution and Venereal Disease. That such Society shall publish a quarterly report or magazine containing articles by the members upon these social questions. That the next reunion of the Conference will be held in 1907 at Brussels and every three years thereafter. That the official seat of the permanent committee shall be at Brussels. That French shall be the official language, but articles in French, German, English, and Italian may be accepted for publication. The following provisional committee on organization was elected: President, M. LEJEUNE, Minister of State, Brussels; vice-president, M. BECO, Minister of Public Health and Hygiene; secretary-general, M. DUBOIS-HAVENITH, agérgé de l'Université de Bruxelles.

III. Resolution presented by PROFESSORS FOURNIER, NEISSER, HUTCHINSON, LESSER, WOLFF, and MRACEK: The Conference holds that a thorough knowledge of venereal disease constitutes one of the most important means of combating the spread of these maladies. The governments are therefore urged to compel the most thorough education of students in this branch. That the instruction should in all cases be given by competent specialists, and there should be instituted in each university complete and obligatory courses upon these diseases. That each government should insist upon a strict examination in these subjects, to be presided over by specialists, as requirement for the medical degree.

IV. That the guardians of orphans be held responsible to the State for the moral welfare as well as the material interests of their charges. That those entrusted with the education of youths will give all possible solicitude to their moral development, which is to include the common-sense principles of temperance, and the cultivation of a high, manly respect for woman, whatever be her social condition.

V. The Conference pleads that the governments use the greatest possible severity in punishing panderers and procurers.

VI. Proposed by PROFESSOR SAUNDBY on behalf of the British Medical Association: The Conference demands of the governments of all countries the establishment of a commission whose duty shall be: (1) To determine the frequency of venereal diseases amongst the civil population exclusive of temporary variations. (2) To inquire into the institutions already in existence for the treatment of venereal disease, the distribution of such hospitals, the number of beds at the disposal of each locality, and the proposal of the most effective measures for treatment of these maladies. (3) The collection of different opinions concerning the best means for preventing and effacing the dissemination of venereal disease among the civil population, and reporting their conclusions.

VII. Proposed by PROFESSOR LASSAR of Berlin: The governments are urged upon all favorable occasions to call the attention of the population, and particularly the young men, to the dangers of prostitution to both sexes and the sinister consequences of venereal disease.

VIII. Proposed by DRS. PIERSON and FIAUX: The Conference recommends that a uniform system shall be used in all countries for the gathering of statistics concerning prostitution and venereal disease.

PROFESSOR FOURNIER rose at the end of the session and proposed that the members of the Conference offer a vote of thanks to the Belgian government for its splendid hospitality and kindness to the Congress, also that an expression of gratitude be extended to the organizer of the Congress, Dr. Dubois-Havenith, and his able assistants, for their untiring and constant efforts which had contributed so largely to its success as well as the pleasure and comfort of the members. This resolution was passed amid great applause, and the Conference ended.

CHARLES WOOD MCMURTRY, MD.

BRUSSELS, September 9, 1899.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Abstract of the Proceedings of the Twelfth Annual Meeting, Held at Indianapolis, Indiana, September 19, 20, and 21, 1899.

FIRST DAY—SEPTEMBER 19TH.

THE Association convened in the Century Club rooms of the Denison House under the Presidency of DR. EDWARD J. ILL of Newark, N. J. An address of welcome was delivered by Mayor Taggart, which was responded to by the President. After the transaction of routine business in executive session the reading of papers was proceeded with.

DR. JAMES F. BALDWIN of Columbus, Ohio, reported

THREE RARE CASES OF KIDNEY CYSTS.

CASE I. *Enormous Hydronephrosis Simulating Ovarian Cystoma.*—The tumor in this case filled the entire abdomen and entered the true pelvis, pushing the uterus to the left. The patient was unaware of the existence of any tumor, but thought she was getting stout for two years. There was no history whatever of any disturbance about the kidney. The enlargement was much more marked on the left side of the abdomen. At the operation the tumor was found to be hydronephrotic, of the right side, and with the entire destruction of all kidney tissue. The blood-vessels had so far disappeared that the only pedicle was an enormously distended ureter resembling a piece of small intestine. The cyst, which was retrocolic, was enucleated without special difficulty, and recovery was uninterrupted.

CASE II.—A large paranephritic cyst, containing about 1½ pints of straw-colored fluid resembling urine. The cyst wall was exceedingly thin, but was successfully enucleated and the cavity closed with temporary drainage. Healing occurred by first intention.

CASE III. *Hydronephrosis of a Retrorectal Congenitally Misplaced and Sarcomatous Kidney.*—This tumor filled the pelvis, pushing the uterus up and pressing so firmly upon the urethra as to necessitate the use of a catheter. The rectum was so pressed upon as to render defecation almost impossible. After separating the tissues the cyst was tapped through the vagina and about one quart of urinous fluid drawn off. The completion of the enucleation had to be made through the abdomen. The specimen proved to be a sarcomatous kidney congenitally misplaced in the pelvis. During the development of the disease hydronephrosis resulted, giving rise to the cyst which obstructed the pelvis. The patient recovered without difficulty and continued well at the time of the report.

While hydronephrosis simulating ovarian cystoma is not excessively rare, paranephritic cysts of any considerable size at least have been very seldom reported. The case of hydronephrosis of a pelvic kidney is, so far as the reporter could ascertain after a somewhat extended correspondence, entirely unique.

DR. JAMES F. W. ROSS of Toronto called attention to a point in connection with the diagnosis of cystic tumors of the kidney, and it was this: Given a tumor that is unilocular by fluctuation, but looks like a multilocular tumor, in consequence of the striæ it is always a tumor of the kidney, and not of the ovary. He believes that if the end of the ureter is tied with catgut it can be left in the course of a nephrectomy, and he does not think it is necessary to follow the ureter down to the bladder.

DR. LEWIS S. MCMURTRY of Louisville concurred in the remarks of Dr. Ross in regard to dealing with the ureter. In a number of cases of nephrectomy that he had performed the ureter was not dilated as much as in the case described by the essayist. In one case particularly he did not attempt to trace the ureter down to the bladder and remove it, but left it and it did not give any trouble.

DR. L. H. DUNNING of Indianapolis directed attention to an important diagnostic point in dealing with cysts of the kidney, namely, the presence of the colon in front of the tumor. He has been able to demonstrate this in large sarcomatous tumors of the kidney, and by pumping the colon full of air the distended colon can be seen running over the outer border or center of the tumor. He has removed three kidneys for tuberculosis. In one instance he did not tie the ureter; he did not dissect and remove it far down toward the bladder, and he had considerable trouble in that case, following it for some time. He thinks it is unsafe in tuberculosis of the kidney to leave the ureter and believes it ought to be removed low down in the pelvis and tied wherever it is left.

DR. J. HENRY CARSTENS of Detroit said that surgeons always had more or less difficulty in making the diagnosis in the cases under discussion, and while the point brought out by Dr. Dunning was a good one, it did not always hold good. He recalled one case in which he supposed he had an ovarian tumor, but found a hydronephrotic kidney as large as that of the first case reported by the essayist. The kidney was very loose and afterward a stone was found in it. The stone was quite large. He believes that when we have a loose kidney which flops around it may grow over the colon, and the colon in some of these cases is behind instead of in front of the tumor.

DR. JOSEPH EASTMAN of Indianapolis (by invitation), stated that he had recently had a case of pancreatic cyst as large as a human head or larger, and it was very satisfactory to notice the ascent and descent of this tumor during inspiration and expiration, a thing not possible if the tumor had been post-peritoneal or connected with the kidney. The pancreatic cyst had distended the mesocolon to such an extent that the transverse colon was very perceptible, lying across in front of the enormous pancreatic cyst; so that the diagnostic point mentioned by Dr. Dunning is applicable to pancreatic cysts.

DR. JOHN M. DUFF of Pittsburg narrated an instructive case in which a diagnosis of abscess of the spleen had been made, but a more careful subsequent examination revealed the fact that the tumor was connected with the kidney, as he had suspected. A median incision was made; the tumor had pushed up the mesocolon; the colon was adherent to the tumor around at the side, and the mesocolon was almost ulcerated through. The kidney was removed through the mesocolon. There was no secretion of urine from the kidney, an examination not

having been made with the Harris instrument for the purpose of ascertaining the condition of the urine from both kidneys.

DR. DUNNING asked as to the reliability of the Harris instrument, to which DR. BALDWIN replied that it was a very satisfactory instrument. He had used it several times in the female.

ECTOPIC GESTATION: SHALL THE PATIENT BE OPERATED UPON AT OR NEAR FULL TERM, THE CHILD BEING ALIVE?

DR. L. H. DUNNING of Indianapolis read a paper on this subject. As preliminary to a discussion of this theme, he reported the history of a case of ectopic gestation of eight-months' duration and operated upon five weeks after the death of the fetus. He said that the proper treatment of ectopic pregnancy after the six month, when the child is still living, is still under discussion. He wrote his paper for the purpose of considering one phase only of the subject, namely, shall operative intervention be instituted during the period of viability of the child, or shall we await the death of the child and the cessation of the active circulation of the placenta, then operate? The settlement of this question he said must hinge upon the relative mortality to the mother of the different procedures. The ectopic infant is of such low vitality and so frequently deformed that if to rescue it greatly jeopardizes the life of the mother, then ethically one must withhold the hand and permit it to die that the greater life may be saved. Such have been the sentiments of the writer for many years. He has had three cases of ectopic gestation at or near full term. In the first, the operation was done during spurious labor at full term. In this case, although fetal movements were detected one hour before operation, the child never breathed after removal by abdominal incision. The mother died the eighth day after operation of hemorrhage, resulting from the removal of the placenta which was left at the time of the initial operation. The placenta was removed thus early in consequence of impending death from septicemia. The other two cases were briefly narrated. A statistical table accompanied the paper. He stated that if the tables given by him approximately show the percentage of recoveries to mothers, then there was an answer to the perplexing and hitherto mooted question, "Shall operative intervention be instituted during the life of the child or only after its death?" We are not compelled to longer consider and weigh the probability of the length of life in days of the child; the safety of the mother alone demands intervention. Undoubtedly other questions will urge themselves upon us, such, for instance, as, Is it less dangerous to operate at six months or nine months? and, What treatment of the placenta yields the least mortality? These are still under discussion. "Is it safer for the mother to be operated upon in a case of ectopic gestation during the viability of the fetus?" The speaker said that in his opinion the statistics collected and compiled by him are so nearly complete and correct that the answer may now be given unqualifiedly in the affirmative. There will be undoubtedly individual cases in which the good judgment of the surgeon will direct him to await the death of the fetus. These will be exceptional cases. The rule will be to operate at or near term during the life of the child.

DR. CARSTENS agreed with the essayist that the proper way, other things being equal, is to operate at once when the child is living and viable. The placenta is not always attached to the broad ligament. Often rupture takes place, and the placenta is attached to the intestine, the colon, the rectum, or the sigmoid, and in cases of that kind it is utterly impossible to remove the placenta when an operation is performed when the child is alive. He had seen such operations performed by other surgeons, and the patients invariably died from hemorrhage.

DR. MCMURTRY thought Dr. Carstens struck the keynote in determining the course to pursue in these cases. By referring to one of the earlier volumes of Transactions of the Association a case reported by him would be found where the fetus had gone to full term, was dead, and some weeks after a spurious labor, when there were beginning septic symptoms, he operated. No fetal movements had been observed for nearly three weeks. The placenta was very large; there was no sign of any atrophic changes in it in consequence of the death of the fetus; it was spread out over one side of the uterus, over the colon and ileum, and there was such a hemorrhage as will obtain from an attempt to enucleate the placenta as never will be seen under any other circumstances at the operating-table. It was perfectly dreadful, the woman being exsanguinated within a minute, the pelvis being full of blood. When the placenta is disposed toward the broad ligament and uterus, as in the case described by Dr. Dunning, he believes there is a good opportunity for complete enucleation of it.

WHAT SHALL WE DO WITH THE POST-OPERATIVE HEMORRHAGE OF CELIOTOMY?

This was the title of a paper contributed by DR. D. TOD GILLIAM of Columbus, Ohio.

Cases of post-operative hemorrhage were cited. The author said he had very little to offer in the way of suggestion. Some time since he had in charge a young lady who was subject to the most violent and persistent uterine hemorrhage of unaccountable origin. She had passed through many hands before coming to him, and he had tried many of the vaunted remedies without avail, as she could not make up her mind to have a curettage, and during one of her spells she fell into the hands of his brother, Dr. Charles F. Gilliam. He placed her on atropin with the result that after the physiological effects of the drug became manifest the bleeding ceased. Since then her attacks have been less frequent and always promptly amenable to the atropin treatment. Other cases followed in the practice of Dr. Gilliam and his brother, among which were some in which the patients had been curetted, and in every instance so far the hemorrhage had been controlled by the atropin. The results had been so convincing in these cases that had fallen under his observation as to force conviction.

As to the modus operandi of atropin he could only speculate. It is known that atropin increases the cutane-

ous circulation, producing a general and marked hyperemia of the surface; it is known that the cutaneous vessels are capable of containing nearly one-half of the blood of the body, hence by derivation it diminishes the amount of blood circulating in the internal organs. The author thinks it quite likely that the vasomotor action which dilates the cutaneous vessels coincidently and by way of equation constringes the visceral vessels. The duodenal ulcers resulting from extensive burns of the skin would argue in favor of compensatory vascularity. It is not expected that this or any other medicinal agent will arrest the torrential hemorrhage of the larger vessels, such as the uterine or ovarian arteries, but is especially applicable to that troublesome form of hemorrhage which emanates from numerous vessels of smaller caliber.

Dr. H. W. Longyear of Detroit said that there is no class of cases more puzzling to him than those which showed the condition of collapse described by the essayist, indicative of internal hemorrhage. And yet there are other conditions which produce the same symptoms, and the surgeon has got to use fine discrimination. If he knows a vessel is bleeding, he considers it his duty to cut down and search for the bleeding-point, no matter what the condition of the patient may be. In a case of ruptured tubal pregnancy, where there is internal hemorrhage going on, it is the duty of the surgeon to reopen and do the best he can. It is not always easy to find the bleeding vessel.

Dr. Rufus B. Hall of Cincinnati stated that hemorrhage or shock could be determined largely by the operator himself. When a patient is put to bed after an operation the surgeon is pretty well aware whether there is great danger of secondary hemorrhage or not. If the operation has been a complicated one and a condition is left which adds to the risk of hemorrhage, this aids the surgeon materially in determining whether or not the patient is bleeding or suffering from shock. He would not hesitate a moment to take out a stitch, after the abdomen is closed without drainage, and he believes without very extensive exploration he could determine readily and certainly whether hemorrhage was taking place or not.

Dr. Edwin Ricketts of Cincinnati said that whenever ligatures are used there is one procedure that is very valuable, one always resorted to by Bantock, that is, crushing the tissues for one-half or one-quarter of a minute by the heavy clamp, and after the removal of the clamp the ligature is applied. The angiotribe, which is being advocated by some operators, in which the ligature is not used at all, is applied and permitted to remain for two and a half minutes, and then removed, and it is claimed no hemorrhage follows its application. The plan, however, suggested by Bantock is one that should not be lost sight of in applying the ligature.

Dr. Robert T. Morris of New York made some remarks on

COCCYGEAL DERMOID FISTULÆ.

The subject of coccygeal dermoid fistulæ is apparently one that has not received very much attention as he finds little reference to it in the literature. Occasionally some one has reported the finding of a dermoid cyst in the coccygeal region, but without making comments on the way in which such cysts are likely to have been formed. He has seen reference to cysts only, but on making a study of the subject he finds that surgeons are much more apt to find fistulæ than cysts. They are more apt to find depressions than fistulæ. In the region of the coccyx not infrequently funnel-shaped depressions of the skin are found. Fistulæ are less frequent, extending to a depth of from half an inch to four inches in his deepest case; and still less frequently wholly encapsulated cysts are observed. The fistulæ and cysts contain straight hairs of the lanugo type mostly, although he has seen some nearly three inches in length, straight, in a mass, and welded together by sebaceous material. The sebaceous material escapes in large quantities from the fistulæ; it remains encapsulated in the cysts and in the funnel-shaped depressions; it frequently dries upon the surface and comes away in the form of scales mixed with epidermis. When his attention was directed to the subject about a year ago he was surprised at finding the proportion of cases in which he noticed these funnel-shaped depressions or fistulæ, or cysts of the coccygeal region, or dermoid cysts. It evidently represents an embryonal defect, and what this defect is he left the Fellows of the Association to suggest. There is a possibility that the tail of the embryo in undergoing involution leaves a portion of the skin highly endowed with embryonal latent cells, and that the skin developing more perfectly in the connective tissues about it, encapsulates, in part or in whole, this absorbing or involuting embryonal tail, so that in a coccygeal fistula we have an inverted tail. He has had four cases of coccygeal fistulæ containing masses of hairs in his practice up to the present time.

In trying to remove them the surgeon must remove the entire cyst-wall or fistula wall, because it consists so largely of embryonal tissue that recurrence takes place promptly following the operation unless this is done. The method of treatment with nitrate of silver and with caustics results only in temporary destruction of the inner layer, just as when surgeons try to destroy bronchial cysts or bronchial fistulæ, consequently recurrence takes place very promptly from the deeper layers of embryonal cells, the latent cells forming the structure again, so that they must be removed entirely. The author cited a case in point and exhibited microscopic slides.

HOUSE TO HOUSE OPERATING.

Dr. Edwin Ricketts of Cincinnati read this paper. The skilled abdominal and gynecological surgeon of today is a product of surgical evolution, to which no man ever gave such an impetus as the great and lamented Mr. Lawson Tait. From him we have learned that the best results depend upon simplicity, thoroughness, rapidity, and rigid cleanliness; that his best work was done in house to house operating.

The advantages are many, and, briefly, are as follows: (1) The greater ability of the general practitioner to attend to the after-treatment, assisted by a competent nurse, the telegraph, and telephone. (2) The absence

of the mental dread of the patient to go into an institution, and the risk therein entailed, a condition by no means to be underestimated. (3) Iron bedsteads and improved household furniture are rapidly finding their way into country homes. (4) God's pure air, and undeniably less liability to infection.

DR. WALTER B. DORSETT of St. Louis said that the word simplicity in surgical work carries with it a great weight. The greatest men are known by their simple way of expressing themselves; and the greatest surgeons are known by their simple way of operating. There are many points that should not be overlooked in regard to the advisability of isolating patients from house to house. In the first place, the surgeon could not maintain the same discipline in a private house that he does in a hospital, whether there be a trained nurse or not, because the friends and relatives of patients are constantly coming in, they carry with them bacteria, and they have a certain amount of influence over the patient. The nervous system of the patient is more or less disturbed, and the recovery in a great measure is retarded. In hospitals a great many things are done that should not be done. Cleansing the hands by different methods is entirely unnecessary; green soap and plenty of it and good hot water are all that is necessary.

DR. J. HENRY CARSTENS regretted that the paper had been read, because he believes that its teachings are wrong and vicious. A great many general practitioners after reading the paper would laugh at aseptic surgery, as well as antiseptic surgery, and they would say there is no use in trying to practise it. When it comes to operating patients do far better in a hospital than at their private homes. A cervix operation or a perineal operation might be done at a private home, but when it comes to doing major operations it is far better to have patients in a hospital, where the surgeon has all the facilities for operating, etc.

DR. WILLIAM H. HUMISTON thought if Dr. Ricketts was taken seriously it would be a backward step of fifteen years. He could not believe that the essayist was serious in all the points he had made. Any one who has seen Tait operate knows that he was the perfection of cleanliness. Bantock was likewise one of the cleanest operators.

DR. WILLIS G. MACDONALD of Albany said that if our present system of operative surgery is correct, if it is based upon the destruction, or better, the evidence of micro-organisms, then the most painstaking technic which can be devised should be followed. He must not dispute the fact that the essayist could operate in almost any private house, but there was no likelihood of his having sterilized water to use about his patient, or about his hands, in any part of the building. In the State of New York people are beginning to appreciate what a good hospital really means; they appreciate what a good training-school for nurses means; they appreciate that they can be made much more comfortable and the chances of recovery are immeasurably increased by going to hospitals instead of remaining at their homes to be operated on.

DR. ROBERT T. MORRIS said the matter had to be settled by statistics after all. The only statistics which he had in mind, were that he had lost eleven appendicitis patients; two of these died in hospital, and nine in house operations. The operations done in hospitals are certainly more than five times as many as those done at private homes

PRIMARY SCLEROSIS OF THE OVARY.

A paper on this subject was read by DR. WILLIAM H. HUMISTON of Cleveland, Ohio. He said there are two distinct pathological conditions now classed as sclerosis of the ovaries, and universally believed to be due to inflammatory changes. There is a primary or non-inflammatory sclerosis, and a secondary or inflammatory fibrosis. These forms can be recognized both clinically and by microscopic examination. In the secondary degenerations is found (in a section taken from some portion of the ovary) a small, round-celled infiltration, or the connective-tissue elements in some of their various stages of development. Also, however advanced the stage of fibrosis may be, the numerical relation of nuclear to cellular elements in this variety is always greater than in the primary form. Thirdly, the microscopic appearances of the vascular system are also different. In the inflammatory group there is primarily a dilatation of the vessels with secondary contractions of their greatly thickened walls and a lessening of their lumen. In the primary group there is usually no thickening of the vessel walls; there is never any dilatation, and contraction occurs so early that one immediately notes the poor blood-supply, particularly to the periphery of the organ. In those cases of arteriosclerosis of the vessels within the broad ligament is usually found the condition extending to the vessels entering the ovary, not otherwise. Lastly, in the primary group the epithelial cells of the ovarian stroma are diminished in number and usually in size. In some sections they are hard to distinguish from the connective-tissue elements, and appear to be undergoing a process of reversion. These several microscopic differences are constant and decidedly marked.

The diagnosis should be based upon the result of palpation of the diseased organs. The cirrhotic ovary is smaller than the normal, is hard and inelastic, and usually deeply corrugated. A sclerocystic ovary is usually larger than the normal organ, and is distinctly globular rather than ovoid. The tunica albuginea is always greatly thickened and is firm and unyielding. The size of the organ is due to the enlarged follicles just beneath the tunica. The hilum first shows the corrugations.

The condition is non-inflammatory and without a history of infection and without signs of peritonitis. It occurs in early life, from puberty to thirty, with dysmenorrhea often since the first catamenia. Amenorrhea or delayed menstrual flow and intermenstrual dysmenorrheic pain, described by every patient as being alike in character and severity with the pains experienced during each catamenia, are constant. This latter symptom differentiates the origin of the dysmenorrhea, making it clearly ovarian rather than uterine in its causation, and in itself is of chief importance clinically.

DR. F. BLUME of Pittsburg, Pa., read a paper, entitled

INTESTINAL ADHESIONS IN SUPPURATIVE PELVIC DISEASE; THEIR SIGNIFICANCE AFTER VAGINAL HYSTEROSALPINGO-OOPHORECTOMY.

The author stated that the time has passed when a surgeon can say without jeopardizing his reputation that he operates exclusively by the abdominal or the vaginal route. Since the introduction of vaginal hysterectomy and the revival of vaginal incision and drainage, our views regarding the treatment of suppurative pelvic diseases have undergone remarkable modifications. We realize that there is no longer but one method of surgical treatment and that, in order to do justice to the patient, we must select that method best adapted to the case. He has seen many women, who, after abdominal section for pelvic suppuration, performed in this country and abroad, were invalids, and he has performed a secondary operation upon a number of them. He has not, however, been called upon to treat a woman upon whom vaginal hysterectomy was performed by another surgeon, nor has any of his patients required or sought treatment at the hands of other operators. His experience is in accordance with the observations of other writers and justifies the assertion that the results of vaginal hysterosalpingo-oophorectomy in suppurative pelvic disease are excellent, notwithstanding the supra-pelvic complications, and there is no class of cases which, as a whole, gives more satisfaction.

(To Be Continued.)

REVIEWS.

NERVOUS AND MENTAL DISEASES. By ARCHIBALD CHURCH, M.D., Professor of Neurology in the Northwestern University Medical School and in the Chicago Polyclinic, etc.; and FREDERICK PETERSON, M. D., Professor of Mental Diseases in the Woman's Medical College, New York. Illustrated. Philadelphia: W. B. Saunders, 1899.

IN spite of its bulky appearance, this work is not a wide departure from the general run of text-books. Indeed, we cannot but condemn the tendency of publishers to sacrifice the convenience of handling for impressiveness of form. If we accept this sacrifice, however, we must admit that this book is a very handsome publication. Excellence of typography, neatness of arrangement and judicious use of italicized words all bespeak praise. To these have been added a profusion of illustrations, which is the chief characteristic of the work, as a book. These illustrations, mostly photographic reproductions, were chosen with admirable judgment, for they are highly descriptive in themselves,

The work is in two distinct parts by separate authors. The division on nervous diseases, written by Dr. Church, occupies the greater portion. While it has been condensed into text-book form, it is, in its way, very thorough. Each chapter shows a careful study of recent literature and the latest pathological data are everywhere included. In the chapter on leptomeningitis and in the excellent, but brief, chapter on sinus-thrombosis, a more extended reference to bacteriological studies would have been a valuable improvement, even in a work of this character. On treatment, also, the text is quite up-to-date, as may be seen in the chapters on infectious and on paralytic forms of nervous disease.

With the exception of the very insufficient paragraph on erythromelalgia, the discussions of the more uncommon affections is ampler than in most text-books. They are nevertheless condensed. On the whole, Dr. Church's work exhibits an amplitude of detail and an accuracy of clinical description that will make it useful to a large number of practitioners, though it is rather too elaborate for students and not elaborate enough for neurologists.

Dr. Peterson's division on mental diseases, is also freely illustrated from very excellent photographs. In the chapter on the general etiology of insanity is reprinted, with a few changes, the author's article on "The Stigmata of Degeneration," from the *State Hospital Bulletin* of July, 1896.

Dr. Peterson's work is interesting in style but it presents no unusual feature and, indeed, hardly does him full credit. In the chapters on the special forms of insanity the following subdivision is employed: Mania, Melancholia, Circular Insanity, Epileptic Insanity, Dementia (primary and secondary); General Paresis, Paranoia, Idiocy, Imbecility, and Feeble-Mindedness. The usefulness of this classification is attested by its adaptability (with very slight amplification) to the needs of the New York State Hospitals for the Insane. The simplicity and elementary character of such an arrangement, however, at once precludes the work from usefulness to the alienist (for whom, be it said, Dr. Peterson did not profess to write it). Similarly the excellent chapter on idiocy deals for the most part with general considerations, the forms of idiocy being dismissed with scarcely more than their mere mention.

VOL. LXXV. NEW YORK, SATURDAY, OCTOBER 7, 1899. NO. 15.

ORIGINAL ARTICLES.

FURTHER OBSERVATIONS ON THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.[1]

BY ROYAL WHITMAN, M.D.,
OF NEW YORK.

AN advocate of the positive treatment of congenital dislocation of the hip often finds himself placed at a disadvantage because of the misapprehension of its nature and its consequences; for the usual conception of the congenital displacement is that it is a form of loose joint which causes a limp, a deformity rather from the esthetic than from the practical standpoint. If, then, the atrophied and displaced muscles and the rudimentary articulation do not at once take on normal function, in other words, if the patient does not cease to limp, the treatment is likely to be classed as a failure. It is well, then, to state at the outset of the discussion, that a dislocation is always a dislocation, whatever may have been the cause.

In the traumatic displacement of childhood there is deformity, fixation, and shortening, and thus great immediate disability which gradually lessens as the displaced parts accommodate themselves to the new conditions. In the congenital form there is a progressive shortening, and usually deformity and limitation of motion, so that in adult life but for the history it would be impossible to distinguish between the two

As the displacement in the traumatic form is immediate and extreme, the time during which replacement is possible is limited to months. In the congenital form the displacement is at first slight, and it progresses slowly; therefore, the time limit may be extended to years.

In the traumatic dislocation the acetabulum is normal and the muscles are competent to resume their functions; thus perfect cure should follow prompt and effective treatment; but if the changes incident to delay make an extensive operation necessary in order to replace the femur, function is almost inevitably impaired. In the congenital form the acetabulum is undersized or misshaped, and the muscles have developed under abnormal conditions, so that perfect functional cure is often impossible.

[1] Read at the thirteenth annual meeting of the American Orthopedic Association, held at New York, May 31 and June 1 and 2, 1899.

The etiology of the traumatic displacement is evident, but that of congenital dislocation must always remain somewhat conjectural. The most reasonable theory, as applying to the majority of cases, is that of intra-uterine pressure upon the flexed thigh; and if, as Heusner's observations would seem to show, the capsule of the hip-joint is more lax and is weaker in the female than in the male, the disproportion between the sexes would be accounted for. If the displacement is present early in intra-uterine life the parts may be considerably distorted; but it is more probable that it occurs at a later period of development, and that at birth it is practically a subluxation; this becomes a complete displacement under the influence of muscular action, and it is confirmed and increased by functional use.

At birth, then, it may be assumed that in a large proportion of cases the replacement of a practically normal femur into an acetabulum of sufficient capacity to contain it would meet with but little resistance, and that if it could be retained for a time in that position development might proceed in a normal manner.

When the child begins to walk, or at a time when diagnosis should be made and when treatment should be begun, the resistance to replacement is not great provided the inlet through the contracted capsule is practicable, but the disproportion between the capacity of the acetabulum, which has meanwhile been deprived of its normal stimulus, and the head of the bone has increased. With each succeeding year at this period of rapid growth the effects of the abnormal use, shown by changes characteristic of strain and pressure upon the head and neck of the femur, the non-development of the acetabulum, the elongation and hypertrophy of the capsule, and the accommodative adaptation of the muscles become more marked, and thus the possibilities of successful treatment are progressively lessened.

That congenital dislocation of the hip is a serious and progressive deformity might be predicted simply from study of the anatomy of the displaced parts, but the fact may be demonstrated by comparing the symptoms and physical signs presented by children in early and in later childhood, for which the larger clinics offer abundant opportunity. From this point of view unilateral dorsal displacement of the hip may be considered somewhat as follows: As the

head of the femur is displaced upward and backward the pelvis is tilted downward and is rotated forward. As a result the lumbar lordosis is exaggerated, and the patient walks, as it were, sideways, one anterior superior spine being habitually in advance of the other. (Figs. 1 and 2.) The yielding capsule does not offer a secure resistance to the weight of the body; thus the limp of a short leg is increased by its elasticity, and by the insecurity of the muscular support, to the peculiar lunge that characterizes the congenital displacement. In early life the articulation is abnormally loose and motion

Fig. 1.

Case III. Showing the inclination of the body toward the shorter leg.

Fig. 2.

Case III. Before operation, showing the abnormal lordosis and rotation of the pelvis.

is practically unimpaired, but with advancing years the shortening is increased by a gradual ascent of the femur on the pelvis, and motion is restricted in extension and in abduction, and finally contractions appear corresponding to the habitual attitude. Even in childhood the relation of the pelvis to the femur has been one of flexion because of its abnormal inclination, and in the adolescent it will be found when the lumbar spine is forced upon the table that the displaced limb is permanently flexed from twenty to thirty degrees, that the range of abduction is very much restricted, and, in many instances, that the actual shortening of displacement, averaging at least two inches, is still further increased by the adduction of the limb. (Fig. 3.)

The earlier and more direct effects of the congenital displacement are the limp and insecurity of muscular support; thus the child is often easily fatigued, and the fatigue may be increased to discomfort on over-exertion. This discomfort is likely to become more noticeable as the weight of the body and the strain of use increase with advancing years. The effect of the strain and friction is very evident in the increased distortion of the displaced parts, as seen at operation on older children, and particularly in the museum specimens from the adult, which, indeed, may be so changed, atrophied, and worn away as to be almost unrecognizable.

In the progress of deformity there are doubtless periods of intermittence, as suggested by depressions in the pelvis worn out by the pressure of the head of the femur, and in certain cases in which over use has been avoided, and especially when palliative treatment by braces has been employed a rudimentary joint of sufficient resistance to hold the femur permanently and yet to allow free motion may be formed, but as a rule the stability that insures comparative comfort is accompanied by limitation of motion and by deformity.

I may anticipate a possible criticism by admitting that patients, in early childhood at least, do not usually complain of discomfort or weakness. This, taken in connection with the fact that the older patients do not often apply for treatment, might seem to be a very effective argument in favor of non-treatment were it not that the same assurance of comfort and ability may be obtained from children affected with almost any variety of chronic disability or deformity, even from those who are distorted by tuberculous disease of the hip or spine. Neither do adults of this class consult physicians except for the relief of actual suffering when the hope of cure has been abandoned. In fact, I think it may be stated that in orthopedic practice, at least, the direct testimony of the patient is of comparatively little value as compared with physical evidence because of the inability of one affected by chronic disability to appreciate the normal standard. This self-deception and unconscious mental and physical accommodation to disability are palliations on which we may count when cure is impossible, but which should not be allowed to deceive one or to excuse the neglect of any possible opportunity to straighten or to strengthen the human machine.

I have considered congenital displacement from the physical and anatomical standpoint and have compared it with the traumatic form in order to present

the subject in a tangible and practical shape, for, as it must be admitted that perfect functional cure is impossible in many instances, it is important that positive treatment should be regarded as a preventive as well as a curative procedure, to be judged, therefore, not by the immediate but by the final results.

It may seem, perhaps, that an elaborate argument is unnecessary to prove that a loose, ill-controlled joint, causing a lunging limp, friction, progressive shortening, contractions and disability is an important deformity and thus worthy of considerable sacrifice of time and labor if it might be ameliorated even, but the statements in the recent text-books and the discussions of societies that may be supposed to shape medical opinion show that the gravity of the disability is not appreciated, and that the shortcomings and the dangers of positive treatment are exaggerated. In fact, at the present time it is rather in spite of medical advice than because of it that the opportunity for treatment is afforded when the chances of cure are most favorable.

Taking all considerations into account, success in the treatment of congenital dislocation of the hip depends, first, upon the proper performance of the operation of replacement and upon the quality of the after-treatment; second, upon the age of the child and the acquired abnormalities of structure and function; and third, upon congenital malformations that are not amenable to correction. Practically speaking, there are at present but two accepted methods of treatment of congenital dislocation of the hip: first, forcible replacement and immediate use—the "functional weighting method" of Lorenz; second, the open operation of Hoffa, as modified by Lorenz.

The functional weighting method was suggested by the operative demonstration that an acetabulum of fair size is usually present in the normal position. If the head of the femur can be passed through the capsular ring and fixed in an attitude of extreme abduction in order to insure stability then the weight of the body forcing it against the rudimentary depression at every step will gradually enlarge its capacity and at the same time the displaced muscles will take on a more normal function. If, however, the replacement is not perfect, or if the opposing bones are not properly fixed in direct contact with one another for a sufficient time, cure by this means is impossible. Of the two, imperfect reposition is apparently the common cause of failure.

All the indications of successful reposition as enumerated by Lorenz, the shock and audible sound of apparent replacement, the fixation in the attitude of abduction, can be produced in almost any case in which the operation is suitable, yet the supposed reposition may be in reality a transposition of the head to the immediate vicinity of the acetabulum, where it lies apparently separated from its proper position by a fold of the capsule. Such cases simulate reposition so closely that only functional use or an examination by the Röntgen-rays will demonstrate the failure, and I am sure that many of the apparent successes that have been reported were in reality of this nature. In fact, I have come to regard it as a preliminary and tentative procedure which, in a large proportion of selected cases even must be supplemented by the open operation. In this sense the treatment is most useful, and it has very great advantages over the older method as the primary operation. For example, it is free from danger and there is no necessity for hospital treatment or even for confinement to bed. Thus the consent of the parents can be readily obtained as soon as the disability is discovered, while as a rule there is a long delay before the open operation is permitted. If the operation

Fig. 3.

Congenital dislocation in an adolescent, illustrating the flexion-contraction in a well-marked case.

is successful there need be but little after-treatment, which is an essential part of the open method, because the muscles regain their function in great part while the limb is supported by the plaster bandage, and there are no contractions or other deformities to be feared. If the operation is unsuccessful it will have served a useful purpose, because the compensatory deformities will have been lessened by the supporting plaster spica, the contractions will have been overcome, and the secondary operation may be more quickly and easily performed when the head of the bone lies in the anterior position. Even if further treatment is abandoned at this stage marked improvement will have been accomplished because the support of the body is more nearly in the normal position, because the shortening has been much reduced, and because the resistance of the tissues about the anterior superior spine checks in great degree the progress of the deformity.

My own experience in this treatment is as follows: I have operated 32 times on 22 cases in 21 patients, in 7 instances two, and in 2 three attempts at reposition having been made on the same patient. The first operation was performed in July, 1896, the last in May, 1899. In 19 instances the displacement was unilateral, in 2 bilateral, in 1 of these cases one, and in the other both hips having been treated. Nineteen of the 20 patients were females.

The patients may be divided into groups according to age: (1) Two years or less, 7 patients, 8 cases. Two are cured and 4 are under treatment, the present indications being favorable. In one case the treatment failed and the open operation was subsequently performed. (2) Between the ages of two and four years, 9. One of these cannot be traced. In 8 the head of the bone was transposed; in 4 of these cases further treatment had been declined and in 4 the open operation was subsequently performed. (3) Between four and nine, 5. One is cured, one under treatment. On 2 the open operation was subsequently performed and in 1 case treatment was discontinued.

The successful cases may be summarized briefly as follows:

CASE I.—*Female, aged nineteen months. Displacement of the left hip. Operation, April 19, 1897. All dressings removed October 11, 1897. No trace of disability remains. (Fig. 4.)

CASE II.—* Female, aged eighteen months. Displacement of the left hip. Operation November 15, 1897. Dressings removed August 3, 1898. A complete cure.

CASE III.—* Female, aged five years. Operation May 20, 1897. A plaster spica bandage was worn until March, 1898, a simple jointed brace with a pelvic girdle until recently. A complete cure. (Illustrated by Figs 1, 2, 6 and 7.)

It will be noticed that a large proportion of these patients were, as regards age, of the distinctly favorably type, yet but 20 per cent. were cured by this method. For this reason I am inclined to look upon it as a preliminary or preparatory treatment in which the prospect of success is dubious except in children at a very early age. I should be tempted to make this statement stronger but for the fact that the third cure was in a child of five years who suffered from a most pronounced and disabling displacement. The case had been under observation for three years before the consent of the parents to

FIG. 4.

Case I. Two years after operation.

treatment could be obtained. At that time the leg was 1¾ inches shorter than its fellow, and the child could hardly walk a block without fatigue and discomfort. She is now as strong as other children and shows no trace of deformity other than a slight atrophy of the hip muscles and a slight reminiscence of the former spinal deviation.

As far as the details of the operation are concerned, the directions of Lorenz have been carefully followed except that manual traction has been used in place of instrumental at the time of operation. This is to be preferred in spite of the labor involved

* Cases marked * were presented for inspection at the meeting.

because the force and pressure can be better regulated. In the treatment of older subjects preliminary traction in bed is preferable to either. When the shortening has been entirely overcome, manually or otherwise, the phenomena of apparent reposition can be produced with ease. In my earlier experience, looking upon these as indicative of actual replacement I supposed the failures to be caused by redisplacement favored by an anterior deviation of the neck of the femur. On this account the short spica was discarded in favor of a bandage including the foot in order to rotate the entire leg inward; but the results were no better than before and it seems more probable that the cause of non-success is the failure to force the head of the bone fairly through the capsular ring. If, therefore, the operation has been properly performed, and if the limb has been retained in proper position in the after

Fig. 5.

Case II. Eighteen months after operation.

treatment, there is little hope of success in repeating the procedure.

At the present time I am very careful to force the head of the bone into its proper position midway between the anterior superior spine and the symphysis, directly below the interior spine of the ilium. In this position it is fixed by a short spica in extreme abduction and in as much inversion as the form of the bandage will assure. There is, as a rule,

Fig. 6

Case III. After operation. Compare with Fig. 1.

Fig. 7.

Case III. Two years after operation. Compare with Fig. 2.

but slight discomfort even after prolonged manipulation and no local signs other than occasional swelling and discoloration about the abductor region and the genitals. The possibility of injury to the epiphysis or fracture of the femur during attempted replacement suggests itself, but of this there appears to be little danger. The cartilage of the head is subjected to some pressure and in several of the cases in which the attempt at replacement had been repeated subsequent inspection at the operation showed minute hemorrage spots beneath the cartilage, and in one case slight irregularity, although the surface was not abraided.

The plaster bandages are renewed at intervals of from six to eight weeks according to their condition. At the first change of dressing it is often impossible to distinguish between a reposition and a transposition, as the measurements of the legs are equal and as one hesitates to move the limb for fear of displacing it. At the second dressing, however, the head of the transposed bone may be distinguished

below the anterior superior spine to the outside of its normal position. Even when reposition is complete success is assured only after prolonged functional use, not even the evidence of a Röntgen picture being proof that the new joint is stable.

The plaster spica is continued for from six to eight months and is then replaced by a flannel bandage or by a simple brace, as used after the open operation. The functional result in successful cases is practically perfect. This is explained by the age of the patients on whom the procedure is likely to succeed because the abnormalities in such cases must be slight and because there is no traumatism inflicted as in the open method.

My own experience leads me to consider the functional weighting operation of Lorenz as quite inadequate as a final treatment for congenital dislocation of the hip. The chances of success are excellent in very young subjects, but they diminish rapidly with age and in older patients it is usually merely a preparation for the open operation.

The Open Operation.—As has been stated, the open operation should be supplementary to forcible correction, yet of the nineteen open operations that I have performed but seven were preceded by the simple replacement, for the reason that the patients were inmates of the hospital and a hospital is manifestly an improper place for a method of treatment that requires many months for its completion.

The manner of operation has been slightly modified from that of Lorenz. The joint is opened by a lateral incision just below and one inch to the outer side of the anterior superior spine. This exposes the fascia, through which the line of junction between the tensor vaginæ femoris and the gluteus medius muscles may be seen. When these are separated from one another the capsule of the joint is at once exposed, often covered in part by the fibers of the iliopsoas muscle. The capsule is opened by an incision in the line of the neck of the femur and through this the head of the bone may be exposed after the division of the ligamentum teres, if it be present. The finger may then be passed through the opening downward and forward to the acetabulum and by its side a strong cervix dilator is inserted with which the capsule is thoroughly stretched, especially the anterior layer which covers the acetabulum. The acetabulum is excavated to the extent that seems desirable by means of a sharp spoon, the bayonet-shaped instrument being the most convenient, after which the head of the bone is replaced. The wound is closed, except for a small gauze drain inclosed in rubber tissue, and a plaster-of-Paris spica bandage including the foot is applied with the leg in an attitude of moderate abduction, complete extension, and slight inward rotation. There is, as a rule, little difficulty in the reposition when the primary operation of forcible correction has been performed or when the accommodative contractions have been thoroughly overcome by preliminary or immediate traction, but in older patients a more extensive division of the capsule may be required. Ordinarily the operation may be performed in less than half an hour, there is little shock, and the subsequent discomfort is slight. As a rule, the patients remain in bed but a week, and are often about in a chair in a few days. In fact, under proper conditions the operation need occasion no particular anxiety. The dangers and difficulties are caused most often by neglect to overcome completely the contractions before the joint is opened so that the long-continued and violent manipulation necessary to accomplish replacement exposes the patient to infection.

The long plaster spica bandage is exchanged for one reaching to the knee in about four weeks and the child is then allowed to walk about. After a month or two the bandage may be replaced with advantage by a light jointed brace attached to the shoe and to a pelvic band. Such an apparatus serves to steady the weak part, to hold the leg in the proper attitude, and it will allow for pressure over the trochanter if desirable.

In many instances the motion which, when the plaster bandage is removed is free and painless, will rapidly become restricted until the leg may be practically fixed, in part by muscular spasm, in part by voluntary effort, and in part doubtless by the changes incident to the repair of the traumatism of the operation, since it may be assumed that the head of the bone lies for a time in contact with the granulation tissue that covers the floor of the new acetabulum and with the wounded capsule.

In certain cases, especially in the younger class of patients, the limitation of motion is slight and transitory, but in the older subjects, particularly when the head of the bone has been completely imbedded in an excavated acetabulum, it may be obstinate and attended by a marked tendency toward deformity. In such cases, it may be noted, there is as a rule no pain or discomfort except on forcible manipulation. In view of the comparative freedom of motion when the first dressing was removed, in several cases I prolonged this preliminary fixation in the plaster bandage without, however, improving the result. It is possible, of course, that if the joint were treated as one would treat disease of the hip-joint, by traction and by removal of weight, this restriction might be lessened, but, on the other hand, it is probable that the pressure and friction of the

head of the femur is useful in preserving and perfecting the new acetabulum. I am, therefore, inclined to believe that rest and fixation for a time estimated to be sufficient for the repair of the injured part, combined with early massage, and if feasible with the hot-air treatment, would hasten the absorption of the products of repair and lessen the restriction of motion, but in any event the tendency toward flexion of the limb must be resisted by frequent manual stretching in the direction of extension, and if necessary by traction at night or even by splinting; for if complete extension is preserved a sufficient range of flexion for all practical purposes is assured. This careful supervision more than all else makes the distinction between a good and bad result in the difficult cases. In any event, restriction of motion is of small importance compared with the security, the improvement in the gait, and the assurance that the progress of the deformity is checked. This theoretical conclusion has been confirmed recently by the testimony of a mother of three children, each having congenital dislocation of the left hip. The eldest, a girl of fourteen, has nearly three inches of shortening with its attendant limp. The second child,* seven years of age, operated upon last autumn, has at the present time not more than ten degrees of voluntary motion at the hip, but the legs are of equal length, and the limp is so slight that the mother proposes to have the third* and youngest child treated as soon as the opportunity offers because the improvement after the operation has been so great even at this stage of the treatment.

The statement that limitation of motion is relatively of slight importance does not apply to the bilateral displacement since even moderate restriction of motion on both sides would interfere very seriously with the ability of the patient, while fixation would be practically disabling. For this reason the problem of treatment is so much more difficult in this class.

In view of the fact that the traumatism of the open operation makes the after-treatment so essential, requiring constant supervision as compared with that by forcible correction, a modified operation suggested itself. On the supposition that non success in the Lorenz or non-cutting operation depends upon the failure to force the head of the bone through the contracted opening in the capsule, one may by the open operation simply cut and dilate the capsule, and then replace the femur without excavating the acetabulum. In two cases, finding the acetabulum of fair size, I employed this method, but in one case there was subsequent reluxation and in the other the head of the bone is not completely contained within the cavity, so that if the method is adopted one should carry out the further steps of the Lorenz treatment by prolonged fixation in the abducted position in order that the acetabulum may be enlarged by the natural means. This intermediate operation seems worthy of further trial.

In another group of cases the restriction of motion usual after operation is absent. This is explained by the fact that the head of the femur is not completely embedded in the acetabulum, but can be felt somewhat more distinctly than is normal, or there may be even an anterior subluxation. This subluxation is favored by the anterior twist of the neck, by the absence of the cotyloid ligament, and by an insufficient depth of the acetabulum. The joint appears to be secure and the shortening of the limb is overcome, but the muscular control of the limb is somewhat imperfect and the limp is prolonged. The most frequent cause of this subluxation is, as has been stated, the anterior deviation of the neck of the bone, which is especially marked in the primary anterior dislocations. This is shown by the fact that in order to place the head completely within the acetabulum the limb must be rotated inward until the inner border of the foot lies parallel with the table. In two cases in which the subluxation appeared after the healing of the wound I divided the shaft of the femur below the trochanter and rotated the distal fragment outward. This corrected the deformity in part, but it was evident from the difficulty experienced in the attempt to hold the upper fragment backward that the osteotomy should either be performed as a preliminary operation or else the limb should be rotated inward at the time of replacement and retained in that position until the parts are sufficiently contracted to hold it within the acetabulum, after which the secondary osteotomy, which would allow the limb to be replaced in its proper relation, might be more easily performed. At the same time, slight abduction of the lower fragment would remedy a depression of the neck of the bone if it were present.

It must be borne in mind, however, that an anterior deviation of the neck apparently prevents the adhesions that cause ankylosis; thus the result in this class of cases would be considered much better than when motion is so restricted as to interfere with function.

Of the 19 open operations that represent my experience in this method of treatment, 15 were performed during the present year so that the time is too short for a report on final functional results. Fifteen of the patients were females, 1 was a male. Ten were cases of unilateral displacement, 5 were bilateral. Of the 5 bilateral cases 3 were operated

upon on both sides, and 2 on one side, making a total of 19 operations. Four of the patients were between seven and nine years of age, 1 was less than three, and the remainder were from four to six years old. In 12 of the 19 cases the ligamentum teres was present, usually attenuated, never hypertrophied. In the youngest child it was absent, in the oldest it was present on both sides. This, it may be noted, is a very much larger proportion than is stated by Lorenz. In all the cases an acetabulum could be distinguished. In 17 cases the head of the bone was nearly normal, usually flattened somewhat on its posterior and inferior surfaces; in 1 case it was markedly deformed, flattened from before backward to an almond-like shape. The direction of the neck is somewhat difficult to determine at the time of operation but there seems to be often an anterior deviation most marked when the dislocation is primarily anterior. In many instances the neck appears to be shortened; in others, it appears to be depressed somewhat (coxa vara) but this again is difficult to determine because the part is so small.

All of the operations were performed at the Hospital for Ruptured and Crippled. There was no death. There was no operative infection of the wound. In one case, the last in order, suppuration appeared during the course of an acute pneumonia, the bacteriologic examination showing that the Fraenkel bacillus was the cause of the infection. This was the only case in which the condition of the patient caused anxiety.

My own impressions of the open operation are that it is not likely to be displaced in the treatment of congenital dislocation. Under proper conditions it is practically free from danger and easy of performance. A certain amount of restriction of motion, even approaching ankylosis, temporary or permanent, may be anticipated when the acetabulum has been excavated and when the head of the bone is contained within it. If motion continues free it will be explained in most instances by a slight anterior subluxation. The points in the treatment that are worthy of further attention are the intermediate operation of replacement without excavation by incising and stretching the capsule, osteotomy for the purpose of overcoming the deviation of the neck, and a modification of after-treatment by which the tendency to restriction to motion may be lessened.

The results of the treatment of congenital dislocation of the hip may be summarized as follows: Forty-one cases have been treated, 22 by the functional method of Lorenz, and 19 by the open operation. On 7 patients both operations were performed. On 7 patients the forcible operation has been performed within so short a time that the results cannot be determined. In 5 instances further treatment was refused. In all of these a transposition of the head of the femur from the posterior to the anterior position was effected so that an improvement may be claimed. Thus there remain 22 cases, or 19 patients, on which a report may be made. In 14 the displacement was unilateral, in 5 bilateral. Of the 14 unilateral cases, 9 may be said to have received the treatment of selection, that is, forcible correction was first performed amd followed when unsuccessful by the open operation. Of this group, in 4* the result is practically a perfect cure, 3 by the simple,

FIG. 8

A successful result after the open operation. (Case IV.) Shows a useful form of brace to be used in the after-treatment.

1 by the combined treatment, or forty-four per cent. (Fig. 8.)

In 2 cases* the result is extremely good, but slight limp remaining; twenty-two per cent. (Fig. 9.) In 2* the result is good; twenty-two per cent. In 1 of these the dislocation was primarily anterior and a subsequent osteotomy was required to correct in part the anterior twist of the neck. In this case the joint is firm and motion is free, but a slight anterior subluxation remains. In the other case there is perfect implantation of the head, but marked restriction of motion. In one case the distortion of the head and neck of the bone was so marked that cure was

evidently impossible. The function has been improved, but the articulation is not as yet firm so that the case is classed simply as improved.

Five patients were operated upon directly by the open method. This group was peculiar in that two of the dislocations were primarily anterior; the treatment was also somewhat experimental, in that in two instances the acetabulum was not excavated In

Fig. 9.

Open operation. (Case XVI.) Eight months after operation.

3 cases the joint is stable and the motion is practically unrestrained; in 1 of these the anterior twist of the neck was remedied in part by an osteotomy: in all a moderate limp remains. These are classed as good results.

In 1 case in which the acetabulum was not excavated there was subsequent reluxation. The patient was re-admitted to the hospital and my successor in the service, Dr. Gibney, replaced the femur by the forcible method and later performed an osteotomy for the purpose of overcoming the deformity of the neck. The record states that the legs were of equal length when she was discharged. In the case in which secondary suppuration occurred* the patient walks with but slight limp, the leg being fixed in an attitude of slight flexion.

The bilateral dislocations have been placed in a group by themselves because the treatment is so difficult, difficult, of course, not in technic, but as regards the individual. In the unilateral displacement the patient has a normal leg to make up for the weakness and insecurity of the other; thus even ankylosis on the operated side would cause comparatively slight disability. But in the bilateral form, at best, the muscles must be inadequate for perfect function for some time after replacement, while even moderate restriction of motion causes considerable disability.

Six patients with bilateral displacement have been treated. One is still in the plaster bandages after the forcible replacement, performed simultaneously on both joints*; the others have been treated by the open operation. In two instances but one hip was treated. In one of these the open operation had already been performed by another surgeon without

Fig. 10.

(Case XVIII.) Bilateral dislocation six months after replacement by the open method. Illustrates the change in the contour of the body.

success. The result in this case is improvement. The articulation is firm and the motion is fair. In the second case, a child eight years of age, the femur is firmly embedded in the acetabulum, but motion is restricted to a range of 10 degrees. The other joint is now under treatment by forcible correction performed by Dr. Gibney.

Three patients were operated upon on both sides. In

one case the result is surprisingly good,* for although the operation was performed but six months ago the deformities of the body have disappeared and the function of the joints is good and bids fair to be perfect. (Fig. 10.)

In the second case the operative result is good but function is imperfect, partly because of the weakness of the muscles and partly because of restriction of motion on the right side. The third case was in a child, eight years of age, and there was an interval of a year between the operations on the two sides. In this case there is but slight motion in either hip and in addition some flexion deformity on the right side so that the functional result is bad. It should be stated that none of these patients has received special care or training other than that provided by the hospital or carried out by the parents. Of the entire list of cases, 34 in number, but 2 of the patients are, I think, at the present time the worse for treatment; all the others have been benefited to a greater or less degree and it may be assumed that the improvement will be increased with the lapse of time.

The object of this paper is to establish the proposition that congenital dislocation of the hip is a serious and progressive deformity for which positive treatment is indicated at the earliest possible opportunity. This treatment is tedious and difficult and the results must be often imperfect, sometimes because of congenital defects, sometimes because of long delay and sometimes because of improper surgical methods, but fairly judged on the evidence presented, the question of the advisability of treatment as opposed to palliation or neglect may be regarded as definitely decided. In support of this proposition I have presented only my own experience because the place of meeting allows me to illustrate it by the patients themselves and thus to direct the discussion toward the question at issue, which is not of the principles of treatment but simply of methods and details by which results may be further improved.

SANITARIA IN THE TREATMENT OF TUBERCULOSIS.[1]

By VINCENT Y. BOWDITCH, M.D.,
OF BOSTON, MASS.

It is most gratifying to note the marked change of opinion that has come in late years among the medical profession in regard to the care of tubercular patients in institutions specially adapted to the purpose. Ten years ago the attitude of most medical men in this country was one of indifference even when not of actual hostility to the idea of segregation of consumptive patients. To-day I think it safe to say that the great majority of the medical profession cordially endorse the idea, the very few exceptions being composed apparently of those who either have not been willing to accept the experience of competent observers or who by habit of mind exaggerate the inevitable imperfections of any human scheme of action and so blind themselves to its manifold advantages.

It is interesting in the study of the history of medicine to read of the experience of the great Brehmer, the father of the idea of sanitarium treatment of phthisical subjects. Forty or more years ago he conceived the idea of establishing a small hospital for consumptives in a mountain village, Görbersdorf in Silesia, where he himself had regained his health. Although ridiculed and scoffed at by members of his own profession, strange as it may seem, he persisted with unflagging energy, and from the nucleus of a small house gradually arose the great institution now known over the medical world, a lasting monument to a noble man. His pupil, Dettweiler, now leads the profession in this special branch of medicine at his great sanitarium at Falkenstein near Frankfort. Numerous smaller institutions have followed the examples of Görbersdorf and Falkenstein not only in Germany but in Austria, France, and Great Britain. It is but necessary to refer to writers in this country to learn interesting details of these various institutions, more especially to the various articles by Knopf,[1] Otis,[2] Solly,[3] Anders,[4] Trudeau,[5] Von Ruck,[6] and others.

In America we have been slow in following the example of the European countries, but the persistent effort of those most interested in the subject has already borne good fruit, and the people of the United States and Canada are beginning to show their characteristic energy by rapidly adopting methods hitherto neglected for combating the ravages of tuberculosis. The reason for this change would seem to be twofold, and I believe it to be due as much to the patient and convincing work of men like E. L. Trudeau in proving to the profession and the laity that patients with incipient phthisis can be cured in sanitaria, as to the growth of the idea of the

undoubted communicability of phthisis about which so much has been written of late years.

Trudeau and the Adirondack Sanitarium need no introduction to you, but to him more than any one else in this country we owe the impetus which has been given to the community at large toward the establishment not only of private but of public institutions for the treatment and cure of consumptives The name of Alfred L. Loomis should never be forgotten in this connection, for it was largely due to his encouragement and energetic work that the sanitaria in the Adirondacks, and later at Liberty, N. Y., were established. Karl von Ruck, at the Winyah Sanitarium at Asheville, N. C.; A. C. Klebs, formerly at Citronelle, Ala.; and, within the last three years, Stubbert, at the Loomis Sanitarium at Liberty—all have had their full share in bringing about the desired result.

The State of Massachusetts has been the first in America, I feel proud to say, to establish a sanitarium for the treatment of tuberculous patients, chiefly consumptives. The institution stands in or near one of our central villages, Rutland, at an altitude of 1200 feet. Protected on the north and west by woodland, it is placed on a gravelly hillside facing the south, the character of the soil and its position favoring excellent drainage. The water-supply comes from an adjacent lake fed by numerous springs. The hospital contains about 180 beds, most of them in open wards which radiate toward the south, like the fingers of the hand, from a semicircular corridor which connects the various parts of the building. It is the aim of the trustees of the hospital to keep it for the treatment of really incipient cases of tubercular disease when there is hope of cure or at least of such amelioration of symptoms that patients may become useful members of society again. It is not intended as a shelter for the hopelessly sick, nor is it to be regarded in any way as a pauper institution. A small price is asked for board, and the class of patients received is chiefly composed of refined people of very limited means. The institution was opened early in October, 1898, and necessarily it is not in the province of this paper to make absolute or positive statements as to what can be done in the future, but I can at least state my beliefs, resulting from my experience thus far at Rutland, and based largely upon results obtained in the last eight years at a very small but somewhat similar institution, the Sharon Sanitarium at Sharon, Mass.

It has been my privilege to be one of the attending physicians at Rutland, and I can truly say that I have been surprised and delighted at much that has been accomplished thus far, not merely in the marked beneficial effect upon the physical condition of the patients, but in the educational influence of the hygienic methods employed there, a fact which I believe to be of inestimable value for the future, and one not yet fully appreciated by those who have had no experience in sanitaria.

In the beginning, serious doubts were felt as to whether we could persuade people of moderate means but of refined habits to enter a hospital in which personal privacy in an open ward is all but impossible. The fear has long since been dispelled, and it has been a surprising and inspiring experience to see the almost universal philosophy and good cheer which prevail under circumstances which might easily be considered depressing. A spirit of good fellowship among the patients is marked, and a sort of good-humored rivalry exists in their endeavors to submit themselves to the methods adopted for their welfare. Open windows even in cold weather are insisted upon as an essential feature of the treatment, and the patients who in a few days do not become not only accustomed to it but even like it are the exception. So marked has this been that in more than one instance patients who have returned to their homes contrary to advice have begged to be taken back because they "could not breathe" in their close houses. Open-air treatment, in short, in conjunction with judicious exercise and plain but nourishing food is the chief feature of the methods employed at Rutland, and the results thus far obtained are dependent upon hygienic and dietetic measures rather that any specific medicinal treatment. Further experience may justify us in trying other methods, but when the results at the end of the year are summarized I can but feel that no matter what other methods are tried, hygiene takes the first place in all our attempts to arrest pulmonary disease.

Having now spoken of the work undertaken by the State, allow me to give you a brief statement of work in the same direction at the Sharon Sanitarium for Pulmonary Diseases, at Sharon, Mass., about eighteen miles from Boston. This institution, still very small both from necessity and purpose, has one feature not common to most sanitaria for the treatment of pulmonary disease, *viz.*, its proximity to a large city near the sea, its location in the harsh, damp, New England climate, and at an altitude of about 350 feet only. It was built in pursuance of an idea long held by my father, Henry I. Bowditch, and later by myself, that by residence in a properly conducted sanitarium near the patients' homes, not far from Boston, much more could be done to arrest pulmonary disease than hitherto, the chief factor being supervision of the patient at the critical

period of his disease when attention to details will make all the difference between a subsequent life of renewed health, and one, to say the least, of invalidism.

Through the kindness and generosity of wealthy people in Boston the Sharon Sanitarium was built in 1891 for the treatment of incipient phthisis arising in women of limited means who could not for various reasons seek distant health-resorts. In this institution each patient has her own special bedroom, there being no open ward, and the same insistence upon fresh air and good food is made as in other sanitaria. The results of my work there during the past eight years I have already given to the medical profession in two papers published in 1894 and 1896, respectively.[1] This spring, in a paper before the American Climatological Association, at its meeting in New York, I gave the subsequent histories of arrested cases of phthisis treated at the sanitarium.[2] From these results I think I am justified in saying that we were not misled in our belief that much more can be accomplished by such methods than by attempting to treat the patients in their homes except in rare cases, and that this can be done, moreover, comparatively near home in a large percentage of cases.

Of the phthisical patients admitted to the Sharon Sanitarium about thirty per cent. have been discharged as "arrested cases." Under the term "arrested" I have classed all those in which cough, expectoration, and fever have ceased with more or less marked amelioration of general symptoms even when abnormal physical signs have persisted, the condition of absolute return to normal conditions, so far as physical signs are concerned in proven cases of tubercular disease, being decidedly the exception in my experience. I have never used the term "cured" believing that the term is unjustifiable until, after the lapse of years, no return of the symptoms is noted. In many of these cases, however, the term now would be permitted inasmuch as a period of more than five years has elapsed without any apparent return of the disease. In my last paper, just referred to, the following results were given: Of the thirty-four patients discharged as "arrested" cases I made the following classification: Class I. Those who have died since leaving Sharon, 6. Class II. Those who have not been heard from lately, 1. Class III. Those who are living, at work, and apparently well as far as pulmonary symptoms are concerned, the period of time since discharge varying from seven years to nearly one year, 24. Class IV. Those who have had a slight return of their pulmonary symptoms, but are still active and from outward appearances, well, 3. The cause of death in these cases may be attributed to one or more of the following conditions: (*a*) Advanced condition of the disease at entrance which under ordinary conditions makes a return of the symptoms probable; (*b*) intercurrence of some other disease without a return of the pulmonary symptoms; (*c*) too early departure from the sanitarium and return, against urgent advice, to the unhygienic conditions under which the trouble arose.

Most of these arrested cases, when studied in detail, are vivid object lessons of the results of care, or the contrary, in the after treatment of such patients. The importance of urgent advice as to the method of life to be carried out by the patient after discharge can not be overestimated, avoidance of the conditions under which the trouble first arose being essential.

As to methods of treatment at the Sharon Sanitarium let me add a few words: Experiments have been made with a few of the so-called "specifics" for pulmonary disease, but my experience thus far has been that they were either absolutely negative in result or possibly slightly beneficial for some of the symptoms of the disease. The inhalation of oil of peppermint has proved at times beneficial for the cough, seemingly, I have thought, more from the anesthetic action upon an irritable throat than from any other cause; otherwise the inhalation or ingestion of the essential oils has been of negative value. Creosote I have found to be of benefit as an aid to digestion, but I have not been able to convince myself of its efficacy in other directions. Antiphthisine per rectum, as at first recommended, proved absolutely negative in my hands. Although tuberculin has been resorted to in another hospital in the earlier portion of its history, I have never employed it therapeutically since. As to the various forms of serum-treatment for tuberculosis, I have thus far refrained from their use at the sanitarium, preferring to test the result of hygienic methods but prepared to resort to other additional means of cure when convinced of their efficacy.

In short, as before stated, abundance of fresh air, judicious exercise in the form of pulmonary gymnastics largely accomplished by means of a pneumatic cabinet, as well as general calisthenics, and the ingestion of plenty of simple, nutritious food, form the base of whatever has been accomplished at the Sharon Sanitarium. Residence in the country, if possible, I regard as one of the most important features of after treatment and when the circumstances

[1] "Three years' Experience with Sanitarium Treatment," etc., *Boston Med. and Surg. Jour.*, July 12 and 19, 1894. "The Treatment of Phthisis in Sanitaria Near Our Homes," *Trans. Mass. Medical Society*, 1896.

[2] "Subsequent Histories of Arrested Cases of Phthisis Treated at the Sharon Sanitarium."

of the patient preclude this, the insistence upon regular exercise and proper ventilation of the home will oftentimes accomplish the desired result.

What I wish to emphasize especially is this fact derived from my experience at Sharon: not only are sanitaria at a considerable distance from our great cities and at comparatively high altitudes necessary and of infinite value but, if the results at Sharon mean anything, such establishments should also be *near all of our great cities and towns* in properly selected sites, for the benefit of those who cannot for any reason go far away. It is for this idea that I wish to specially plead here as I have elsewhere before.

You are to be congratulated upon the recent establishment of the beautiful new sanitarium at Muskoka and I trust it may be the beginning of a series of similar institutions. At the same time within short distances of your large cities I believe you can also establish sanitaria which will accomplish similar results.

Hitherto we have spoken only of sanitaria meant for the cure of incipient phthisis, but equally important and necessary are hospitals for the hopelessly ill within easy access even if not within the immediate confines of our cities. So much has been written upon this point of late that it would seem hardly necessary to do more than emphasize the manifold advantages of such institutions. By the removal of hopelessly ill consumptives from our overcrowded, unhygienic poor districts we not only take away probable sources of infection but place them where proper care may be given, at the same time relieving the families and friends of burdens which they can ill afford to bear.

If we can convince our legislators and our private citizens of the incalculable value of such measures we shall have done much, as another generation I believe will show, toward diminishing the inroads of the great scourge of the human race. Surely that is an incentive to work.

VAGINAL CELIOTOMY: ITS SCOPE AND LIMITATIONS.[1]

By J. RIDDLE GOFFE, M.D.,
of New York;
Professor of Gynecology in the New York Polyclinic Medical School and Hospital; Visiting Gynecologist to the New York City Hospital.

In the evolution of the vaginal method as a route of attack in the surgical treatment of pelvic disease we have now reached that stage in which it is no longer confined on the one hand to simple puncture and drainage, nor limited on the other to the inevitable, radical operation of hysterectomy. Experience has gradually broadened the application of this method to various conditions in the pelvis and with the improved technic has so facilitated the work that in the hands of the expert the condition must be extremely rare that is not amenable to it.

There are two vaginal incisions through which the pelvic cavity can be reached: one posterior to the cervix into Douglas' pouch and the other anterior to the cervix, separating the bladder from the uterus and opening up to view and touch the entire contents of the pelvis. The latter incision is the one which affords the greatest facility for operative procedures and the one which I use almost exclusively, the posterior incision being sometimes used in connection with it to afford additional opportunity for manipulation and in some cases for the purpose simply of securing drainage. Briefly, the procedure consists in making a tranverse incision through the anterior vaginal fornix, corresponding to the incision employed in complete vaginal hysterectomy. In addition to this a longitudinal incision is made at right angles to it through the entire length of the anterior vaginal wall. The bladder is then dissected from the uterus and also from the vaginal wall to the extent of an inch or an inch and a half on each side of the longitudinal incision. Through this opening, whether in virgin or multipara, ample space is afforded for whatever radical or conservative work upon the uterus and its appendages may be indicated.

The simplest and at the same time the very important function which is subserved by any incision into any of the large cavities of the body is that of an exploratory operation. An exploratory incision, so far as possible, should be free from danger; should give facility for gaining the desired information and at the same time afford opportunity for the completion of such surgical procedures as the indications may require. The anterior vaginal incision fulfils these functions most satisfactorily. First, it is free from danger and devoid of untoward or annoying consequences. When I first began to employ this method I feared that it would be followed by more or less serious bladder symptoms. In this, however, I have been happily disappointed; indeed, I have yet to meet the first case in which there has been any symptom referable to the urinary apparatus. The tissues through which the opening is made seem to be unusually tolerant of traumatic interference and the generous blood supply of these parts favors prompt and complete healing. As an exploratory incision I have found it to afford the means of acquiring definite and reliable information in regard

[1] Read at the twenty-fourth annual meeting of the American Gynecological Society, held at Philadelphia, May 23, 24, and 25, 1899.

to the entire contents of the pelvis. The third consideration is the important one, and experience alone can reveal how wide is the scope of its application.

During the past three years I have treated in this way almost every condition to be met with in the female pelvis—indeed, so thoroughly has the method commended itself to me that with three exceptions I have used it in every case that has come before me for operation. These cases have embraced every variety of disease from simple retroversion with adhesions to prolapsed and cystic ovaries, unilateral and bilateral salpingitis, ectopic gestation, fibroid tumors of the uterus, and dermoid cysts. This method affords opportunity for the most complete and radical work and at the same time lends itself to every form of conservative work upon the uterus and its appendages that has been suggested in the trend of recent modern gynecology. In no case have I yet consummated the operation of myomectomy, but in one instance this conservative measure would have been employed had it not been for the multiplicity of small tumors which contraindicated its application.

In cases of simple retroversion of the uterus the organ is readily anteverted and delivered into the vagina. The appendages first of one side and then of the other readily follow after and are carefully inspected and subjected to whatever treatment may be indicated. The round ligaments are then shortened by simply looping them upon themselves and stitching the loops together and the vaginal incisions closed with a running catgut suture. This procedure has its most appropriate application in cases of retroflexion in unmarried women. Its advantages are that the healing process goes on unconsciously to the patient, without any more constitutional or local disturbance than normally attends a simple trachelorrhaphy. The patient herself is not conscious of even having had an incision made, nor does she bear upon her person any trace of a surgical operation. Indeed, in many instances, the wound heals so kindly that often an expert gynecologist even after the lapse of only a few months might examine a patient and never suspect that an incision had been made.

In cases of retroversion with adhesions of the uterus and appendages the adhesions are promptly broken up, the uterus and appendages delivered into the vagina as before, and such treatment applied as may be indicated.

In cases of enlarged and cystic ovaries it is my custom in certain cases to excise the degenerated tissue, and in other cases, in which so extreme a measure is not indicated, to apply the ignipuncture, making in some cases as many as ten or twelve punctures with the actual cautery. When the indications demand it one ovary and tube are removed and such conservative work as may be indicated is applied to the opposite appendage. It is my effort and custom in cases in which the conditions justify it to leave a part of one ovary and at least the stump of the corresponding tube. In passing I may say that my experience in this conservative work grows more and more satisfactory. Four patients upon whom varying amounts of conservative work have been done have conceived and borne children, and satisfactory relief from pelvic symptoms has attended the other subjects to a gratifying degree. Large pelvic abscesses involving the tubes and ovaries, buried in exudate and firmly adherent to surrounding tissues, including both the intestines and the omentum, are easily, quickly, and satisfactorily dealt with and with far less shock to the patient, and a much smoother convalescence than formerly attended my work when done through the abdominal incision.

Large cysts of the ovary, simple and colloid, are easily handled through this incision when free from adhesions in the abdominal cavity. When its contents have been evacuated the cyst will collapse and can readily be drawn through the vaginal incision. In dealing with firm and extensive adhesions the danger of injuring or tearing the intestine is always imminent. Experience, however, educates the sense of touch and makes it possible for one to differentiate the various structures when they are not in sight and thus avoid doing harm. In only one case has an accident of this kind happened to me. In that instance the condition was one of large double abscess of the ovaries with extensive adhesions to the omentum and intestines. In separating the latter on the left side the sigmoid flexure was torn and a large opening made into the gut. Under the circumstances it seemed wise to me to perform a laparotomy and treat the wounded intestine from above. The laceration was found to be very extensive and required the resection of fully four inches of the sigmoid flexure. An end-to-end anastomosis was performed, however, and the patient made a smooth recovery. It must not be forgotten in this connection that such accidents are not by any means infrequent in dealing with similar conditions through an abdominal incision even in the hands of the most careful men. But if ninety per cent. of pelvic disease can be treated successfully without resorting to laparotomy, just so many women are saved primarily from the dangers of a laparotomy and, secondly, from all the discomforts which that incision involves as well as the more remote danger of hernia.

CLINICAL MEMORANDUM.

FRACTURE OF THE FEMUR: CONVALESCENCE COMPLICATED BY AN X-RAY BURN.

By J. COPLIN STINSON, M.D.,
OF SAN FRANCISCO, CAL.

M. R. always enjoyed good health until February, 1898. In July, 1897, he went to the Klondike and located at Dawson City. About February 15, 1898, he began to feel stiff and sore in his legs, and on February 24th entered St. Mary's Hospital at Dawson City with scurvy. The skin covering his feet, legs, and back of his thighs was ecchymotic. He remained in the hospital until June 26, 1898, and when he left weighed forty pounds less than when he entered it. He reached San Francisco July 17, 1898. By October, 1898, the black discoloration had disappeared from his legs and he felt perfectly well. On October 31st, while bicycling he was thrown violently from his wheel and the right thigh near the hip-joint was fractured. He was taken to the receiving hospital where chloroform was administered and the bone set. On November 1st the right hip-joint and adjacent portions were examined by means of the X-ray. The skin was exposed to the rays for forty-five minutes. On November 2d, skiagrams were again taken, the parts being exposed for the same length of time as before. During the exposures the dressings were removed from the region of the joint. The leg was kept extended by weights. On November 3d a long iron splint was applied along the outside of the body, reaching from the axilla to the foot.

Three weeks after the fracture occurred a plaster cast was applied. About six weeks after the X-ray examination the patient noticed considerable purulent-looking fluid under the plaster in the inguinal region. The plaster was cut away over this area and the skin exposed. The skin had exfoliated, looked parched, was of a dark-brown or coffee color, and purulent fluid covered the wound beneath the skin. A piece of skin the size of one's hand was removed. At first there was no pain, but later it was very severe and of an aching, throbbing character. Applications of medicaments other than vaselin caused great distress. By January 4, 1899, the wound appeared healed, but a thick, hard, dry, firm adherent scab about the size of a dime formed in the center of the healed area. This did not dry up or drop off but remained about the same size until the middle of February, when it began to extend and involve the surrounding skin.

On April 25, 1899, I was called in. I found the patient's general health excellent. Over the center of Poupart's ligament in the right groin I found a large, dry, leathery slough involving the skin and subcutaneous tissues. It was oblong in shape, about two inches in a vertical direction and two inches and a half in the transverse and was firmly adherent to the underlying structures. The skin for about an inch around the slough was thickened and very much indurated. I tried to remove the slough with scissors and forceps, but it was so tough and so intimately adherent, extensive, and painful on manipulation that only a few small pieces were trimmed away. I ordered hot, moist, borated gauze, several layers in thickness, to be applied to the wound. The gauze extended on all sides far beyond the edges of the indurated skin and was covered with a thick layer of moist cotton and a layer of gutta-percha tissue. On the top of this a couple of hot-water bags were placed to maintain heat and moisture. The bags were changed as often as the water began to lose its heat. The gauze was changed three times a day. At times carbolized gauze wrung out of a 1 to 100 solution of carbolic acid was used instead of the borated gauze. This application relieved the pain somewhat while the borated gauze promoted more rapid healing. There was considerable pain at all times until healing was completed. The applications were continued without intermission until August 3d. The sloughs had come away completely by June 15th and the indurations had all disappeared. Healing was complete by August 30, 1899. A small, moist gauze pad and sheet of rubber tissue were retained over the groin for about a month longer. At the present time the patient's general condition is excellent. He weighs 200 pounds. The scars in the groin are smooth, soft, and solidly healed.

MEDICAL PROGRESS.

Diagnosis of Aneurism of the Thoracic Aorta.—FRANKEL (*Centralbl. für Inn. Med.*, August 5, 1899) confirms the importance of Oliver's symptom in the diagnosis of aneurism of the thoracic aorta. It is especially marked when the aneurism occupies the third portion of the aorta and comes in contact with the wall of the trachea and left bronchus, and also in aneurism of the anterior portion of the arch where it crosses the anterior tracheal wall, provided there are adhesions between the aorta and the trachea at this point. Oliver's symptom consists in a systolic downward motion of the larynx. It can best be observed in the following manner: With the patient's head well bent backward and his mouth closed, one grasps the thyroid cartilage between the first and middle fingers and draws a little upon it from below upward. When this is done the downward thrusts of the larynx can be distinctly felt. Cardarelli has modified this test by pushing the larynx from right to left, the patient's head being meanwhile in a normal position. The thrust of the larynx under these circumstances will be from left to right. Frankel looks upon this test as pathognomonic of certain forms of aneurism of the arch of the aorta when other signs do not appear. It is conceivable that the same sign might be produced by a mediastinal tumor, although there is no clinical evidence of it.

Fatal Result of Ligation of the Internal Jugular Vein.—KUMMER (*Centralbl. für Chir.*, August 12, 1899) performed an operation upon a patient, aged fifty-two years, for the removal of a follicular cystadenoma of the lower jaw. The right half of the jaw was resected, a temporary ligature being placed upon the external carotid above

the superior thyroid branch. As the operator was dissecting out a nodule in close proximity to the internal jugular vein this vessel was so badly injured that it was tied in two places and divided. The operation lasted three-quarters of an hour, and for three hours afterward the pulse was strong and regular, but gradually became small and quick. Death occurred five hours after the operation. The autopsy showed intense congestion of the base of the brain with extravasation of blood in the ventricles. Death was attributed to obstruction of the circulation caused by ligation of the internal jugular vein. Rohrbach has described a similar case in which death resulted seven days after ligature of the internal jugular. The autopsy in that case showed a hyperplasia of the jugular vein of the other side of the neck, which fact plainly showed how great a venous stasis was produced by the ligation. Kummer expressed the opinion that in his case the temporary ligature upon the external carotid reduced the power of resistance of the middle meningeal, and so acted as a contributing factor in the death of the patient.

The Treatment of Delirium Tremens by Cold Baths.—Letulle (*Rev. de Therapeut.*, August 15, 1899) prescribes cold baths at a temperature of 72° F. for patients suffering from delirium tremens with high fever, 40.3° C. (105° F.). He gives an account of a patient who was immersed and thoroughly rubbed during the bath, which lasted thirty minutes. The talkative delirium persisted without any modification for twenty-five minutes. At the twenty-eighth minute he grew somewhat calmer and became visibly cyanotic. At the thirtieth minute he was taken out of the bath in a stupor. He was rubbed dry and artificial heat was applied. During the bath the pulse varied from 100 to 112; after the bath it remained at 108, but the temperature, taken by rectum, had gone down to 33.7°. C. (92°F.). Stimulants were administered, including 6 hypodermic injections of ether. At the end of an hour the temperature began to rise and the talkativeness returned. Several small doses of morphin were given hypodermically, in all 1 grain in twelve hours. On the following day the patient was much depressed but calm, and in a week he was quite restored. Similar results following a prolonged cold bath have been reported by other writers, one of whom in a very grave case kept his patient for seven hours in the water. Digitalis, opium in large doses, chloral, etc., never produce rapid or decisive effects; therefore, he is in favor of treating every patient suffering from delirium tremens by baths at a temperature of 72° F., lasting from ten to fifteen minutes to two or three hours, according to the gravity of the case, and until there is complete cessation of the delirium and fever. He looks upon restraint of such patients by the *camisole* as a species of homicide.

Massage with Quicksilver.—Rindfleisch (*Münch. Med. Woch.*, August 22, 1899) has devised a plan by which one can massage rheumatic joints without doing them more injury than good. He takes the inflamed hand and sinks it in a deep, wide glass which is two-thirds full of quicksilver. The quicksilver exerts an equal pressure on every portion of the fingers, and this increases very rapidly as the fingers sink further into it. The hand is sunk slowly into the quicksilver and withdrawn twenty or thirty times at one sitting. After the second sitting he was pleased to observe a marked diminution in the swelling and in four days the joint was almost normal. The method recommends itself for wider trial.

Idiopathic Thrombosis of the Portal Vein.—Rogers (*Bristol Med.-Chir. Jour.*, June, 1899) reports a thrombosis of the portal and contributory veins—a condition which occurs most infrequently. The patient was a child not quite five years old, who had been ill for three months with increasing abdominal distention. There was no personal or family history of syphilis. There was a small amount of free fluid in the peritoneal cavity and an enlarged spleen. There appeared to be no abnormality of any other organ. Four months later the child vomited some blood. Examinations showed that the spleen was still large and the liver extended two inches below the costal margin. Three years and eight months later the patient was re-admitted to the hospital, the parents stating that he had passed blood by the rectum. The following month he vomited bright blood several times and passed black blood per rectum. This occurred at long intervals for three months. For many months afterward he was free from hemorrhage and then had so large a hemorrhage that he almost died. He recovered from this attack and the hemorrhages were repeated every week or two until the patient died from exhaustion a little more than seven years from the time of the first symptom. During all this period the physical condition did not vary. A small amount of fluid was always present in the abdomen and this appeared to increase just before active hemoptysis came on. The spleen reached to within a half inch of the umbilicus but the liver apparently returned to its normal size. Traces of albumin were occasionally observed in the urine and there was an anemic cardiac murmur. The patient had a peculiar earthy odor. At autopsy there was found a small quantity of fluid in each pleural cavity. The lungs were healthy. The heart was small and partly empty. There was no valvular disease. The greatly enlarged spleen was adherent to the diaphragm and stomach. The splenic vein was filled with a hard discolored clot and a complete new set of vessels had developed which led from the spleen at various points. Tracing the affected vein forward the clot was found to extend to the vein in the lesser curvature of the stomach and to compensate for the obstruction to the circulation large veins coursed across the stomach from the right gastro-epiploic. One branch of the superior mesenteric was involved in the clot and the plexus of veins known as the pancreatico-duodenal was also affected. The portal vein as it entered the liver was hard and cord-like but the clot did not extend to any depth, although no compensatory branches were observed. The inferior mesenteric was not affected. Only a few similar cases have been reported. In these the duration of the trouble was usually only a few weeks. The cause of thrombosis is obscure. The liver is to a certain extent starved under such conditions but does not become cirrhotic. The writer believes in treatment by hemostatic drugs.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, OCTOBER 7, 1899.

THE REGULATION OF VENEREAL DISEASES.

We presented in our columns last week a most interesting account from our foreign correspondent of the proceedings of the International Conference on Syphilis and Venereal Disease recently held at Brussels. With the great advance during the past few years in our knowledge of these diseases, especially gonorrhea, it was hoped that some plan might be devised by which with concerted action throughout the world these scourges of mankind might be restrained. Indeed, Neisser went into the Conference inspired by the belief that the time has come when it is entirely practicable for the medical profession supported and assisted by the police, working under proper sanitary laws, to begin the process of suppressing venereal disease. Unfortunately, the moral phase of the question obtruded itself, and the discussion promptly degenerated into a heated debate for and against the general subject of the official recognition of prostitution.

The Conference debated for two wrathful days over the problem "Have systems of regulation had any influence upon the frequency and dissemination of syphilis and venereal disease?" and the disputants were so far from coming to any conclusion whatever that the President declined to put the question.

The fact of the matter simply is that we have absolutely no accurate or reliable statistics as to the actual amount of venereal disease in a community, so that comparisons of "before" with "after" or "regulated" with "non-regulated" are simply waste of time. Nor, unfortunately in the nature of the case, are we ever likely to have a complete or even approximately accurate record. The chief aim of the victims of venereal disease is to conceal its real nature, and even if physicians could ever be induced or compelled to report every case coming under their care, this would simply mean the driving of more than half the patients to the care of quacks or to home treatment by advertised "sure cures," so that reports under compulsory notification would be no index whatever of the actual prevalence of the disease.

Syphilis and gonorrhea cause few deaths, and, even in the rare instances in which they do a medical man who would dare to record the name of either in a death certificate would be either lynched or ostracised. So there seems little prospect of any more reliable data in the future than at present.

And the same difficulty is met upon the other side of the problem, the effect of registration upon the number of prostitutes. Usually after registration both the number of prostitutes and the percentage of disease among them show an apparent diminution. But then obviously much of this improvement is delusive, if, indeed, it be not overbalanced by the number of "regulars" who have simply joined the ranks of the clandestines and escaped all supervision. So we have not the data to pronounce positively even upon these two great fundamental questions, Has the amount of venereal disease in the community increased or diminished in the past ten, twenty, or forty years, and Is the number of prostitutes increasing or diminishing? But that is just why both sides are so positive. It is like a religious discussion in which anything can be asserted in perfect confidence that it can never be positively disproved.

The profitable features of the Conference were the awakened interest in the subject in general, and the

positive and optimistic views of those great masters, Neisser, Fournier, and Jonathan Hutchinson, that positive treatment, early begun and vigorously prosecuted, robs both syphilis and gonorrhea of their terrors for the individual victim and their dangers for his associates as well as his posterity.

THE TREATMENT OF GRAVES' DISEASE AND SOME ALLIED CONDITIONS.

IT is becoming clearer from year to year that Graves' disease is not so rare as was at first thought. It is also becoming clear that there is a series of symptomatic conditions which, while they do not present the full clinical picture of Graves' disease, are allied to it in many ways. These larval forms are often developed on the basis of a severe neurasthenia, and are the result not infrequently of chronic gastro-intestinal disturbance with consequent autotoxemia. In the atypical forms, while the tremor and the tachycardia are present, the exophthalmus is often absent, and the enlargement of the thyroid oftener still.

The fact has been pretty generally accepted that some fault in the secretion of the thyroid gland is the fundamental cause of Graves' disease. That the symptoms are due to an excess of thyroid secretion is as yet only a theory, and whether the influence of the thyroid is directly exerted upon internal nutrition by throwing into the circulation an excess of some toxic principle or keeping out some sozic material that neutralizes toxins, and so disturbing the chemism of general metabolism, is not definitely known. Certain features of the disease to which a good deal of attention has been directed in recent years would seem to indicate that the influence of the thyroid is indirect, and is exerted at least partially through the gastro-intestinal tract. Besides the intermittent diarrhea so characteristic of the disease there are other symptoms from the digestive tract, such, for instance, as capricious appetite, gastro intestinal uneasiness, and the presence in the urine of certain products, as indican, that are supposed to indicate disturbance of intestinal digestion and absorption.

The invariably unfavorable prognosis that used to be given in connection with Graves' disease has been greatly modified by the reports of many recent observers. Dr. Janeway, in a late number of the MEDICAL NEWS (August 26, 1899) said that in his experience patients suffering from the disease in private practice get well, though in hospital experience the results have not been so good. His treatment consists in assuring the patient that the disease is not as he has perhaps been told, incurable, the improvement of his general nutrition, and the administration of strophanthus and iron. When edema occurs digitalis is given in addition to the strophanthus.

Professor Mendel, the distinguished neurologist of Berlin, has long insisted that he is able to cure practically all the patients with Graves' disease that come to him for treatment. His plan is that outlined by Dr. Janeway, with the additional advice to the patient that a great deal of rest must be taken, twelve to fourteen hours of sleep a day, and a plentiful, but as far as possible unirritating, diet adhered to. Large quantities of milk, five or six or more liters in twenty-four hours, are recommended. In general, it is the rest-cure, but without confining the patient to bed. Owing to the strong nervous element in the cases Mendel insists that the patients shall not be liable to sources of worry and annoyance, and when marked excitability exists he counsels the use of the less depressant nerve sedatives.

One is tempted to class the treatment of Graves' disease, suggested by Dr. Allen of Edinburgh in the London *Lancet* for August 26, 1899, under this same category as affording relief by amelioration of the gastro-intestinal condition. He found in a case of the disease that the urine was very light in color and the dejecta pale. He concluded that there was a paresis of liver function, and administered pig's bile, using altogether 48,000 grains. Some 3000 grains of this was administered hypodermically, nearly 1000 grains directly into the thyroid gland. He thinks that it served to neutralize certain toxic substances produced by the gland. His patient improved mainly, as he admits, because of the effect of bile taken by the mouth. In another case the same result followed.

These observations would seem to confirm the opinion that whatever may be the direct pathogenic basis of Graves' disease treatment of the gastro-intestinal condition is always the principal indication. In most cases in which the treatment can be thor-

oughly and successfully carried out, it will effect not alone an amelioration of the symptoms, but will, in the opinion of at least two great and careful clinicians, bring about a positive cure of the disease under favorable conditions.

COPYRIGHT IN LECTURES.

A recent decision of the English High Court of Justice is of the greatest interest to medical professors and lecturers because it involves their right to what they have spoken. The case was a very important one, the defendant being no less a person than Lord Roseberry, the ex-Premier of England, while the plaintiff was the *London Times*. The noble lord in furnishing speeches for a forthcoming volume, "Appreciations and Addresses," to his publisher, John Lane, copied almost verbatim the text of certain speeches from the parliamentary reports of the *Times*. The *Times* brought suit to restrain publication of the volume contending that its report of the speeches was covered by copyright, and that the speaker had no right in the premises so far as the form of the speeches went.

The decision was rendered in favor of the *Times*. The argument of counsel was that unless a man takes the usual steps to secure the copyright on a lecture before its delivery, once it is delivered it becomes public property. As to the rights of the newspaper in the matter it is conceded that it is the reporter who gives form to the matter, and it is in this that the copyright lies. The reporter corresponds to a translator from a foreign language, and just as a translation may be copyrighted so may the report of a speech.

As American law follows English law very closely in this matter, it is evident that those who are present at medical lectures may bring out such lectures and secure a copyright on them. Of course a lecturer has his protection in being able to secure a copyright before the delivery of a lecture, but he may seldom be in a position to have his lectures in such shape as to take advantage of this right.

He may, however, copyright certain important lectures of a course before their delivery, so that the set would be noticeably incomplete without them, and thus secure the same object as in copyrighting the whole course in advance.

ECHOES AND NEWS.

A Pasteur Institute at Vladivostok.— A large building has been completed at Vladivostok, Russia, to serve as a Pasteur Institute for the cure and study of various epidemic diseases. It is thought that this frontier town will afford unusual opportunities for study.

Lombroso Has Found a Normal Genius.—Professor Lombroso has at last discovered a man of genius whom he can acquit of the charge of insanity. It is the memory of Goethe which he has thus honored in a recent article in an Italian literary journal. Goethe, he considers, was a normal, healthy and sublime poet.

Dr. Davenport Appointed Professor of Embryology.— Dr. C. B. Davenport of Hartford has accepted the professorship in embryology in the Deparment of Zoology at the University of Chicago, which was made vacant by the resignation of Professor William Morton Wheeler, who has gone to the University of Texas.

Death of Dr. Hendricks.—Dr. George A. Hendricks, Professor of Anatomy in the University of Minnesota, died at Minneapolis on September 25th. Dr. Hendricks went to Minnesota in 1889 from the University of Michigan. He introduced into the latter institution the graded course in anatomy, of which he was the originator.

Surgical Instruments Not Dutiable.—The *Railway Surgeon* for August 22d publishes a recent decision rendered by Judge Colt, of the United States Circuit Court reversing the decision of the Board of Appraisers and holding that surgical instruments imported into this country, being "scientific instruments" within the meaning of the law, are not dutiable.

How Quarantine Laws Are Administered by the U. S. Marine Hospital Service.—The Marine Hospital Service which has charge of the quarantine at Savannah, Ga., recently arrested two men from Philadelphia for making false statements regarding their itinerary and had them fined $50.00 each. They had been in a section of the country where there was liability to yellow-fever contagion.

Christian Science Exposed.—About one year ago the Medical News undertook the thorough investigation of the practices of Christian Science, placing the work in the hands of Dr. John B. Huber. The results of these investigations were published in the Medical News beginning with the issue of January 21st and continuing in three succeeding numbers. We are pleased to note that Dr. Huber has extended his inquiries, and now publishes in the October number of *Appleton's Popular Science Monthly* a most convincing and readable summary of his work.

A Prize for an Essay upon Tuberculosis.—A prize of a thousand dollars was offered by the Tuberculosis Congress recently held at Berlin for the best essay on the subject "Tuberculosis in the Community and Its Prevention." The essay must be written in a popular manner

If two authors are equally successful the prize will be divided between them. Competitors must submit their manuscript before December 4, 1899, to Professor B. Frankel, Berlin, Bellevuestrasse 4. The essay must be signed with a fictitious name and the real name and address of the writer be enclosed in a separate envelope.

Introduction of Yellow Fever into Key West.—In view of the allegations published in several newspapers, purporting to have eminated from official authorities of Florida, to the effect that the present epidemic of yellow fever in Key West is due to the "negligent inspection service of the Marine Hospital Service" at Havana and no disavowal by said authorities having been received or noted in the press, the Bureau deems it necessary to state that it knows of no evidence or facts which justify such assertions. The alleged facts and intimations, so far as known, have been thoroughly investigated and found to be without foundation.

A Fertile Hybrid Pigeon.—Professor C. O. Whiteman, of the Department of Biology at the University of Chicago, is reported to have succeeded in raising a fertile hybrid pigeon. This means the making of an entirely new species of pigeons and is a scientific achievement which had been supposed impossible. Dr. Whiteman, early in the summer cooped 300 pigeons in wooden cages and shipped them to Wood's Holl, Massachusetts, where the discovery was made. These pigeons were from various places and were both wild and tame. The mother of the hybrid bird was a Japanese turtle-dove and the father a common rough pigeon.

Japanese Medical Literature.—The Sei-I-Kwai Medical Society of Japan, or in other words, the Japanese Society for the Advancement of Medical Science, keeps on file in its library between thirty and thirty-five native publications devoted to medicine, besides as many foreign medical journals. The society also publishes a medical journal of its own, and part of the articles are in English, to meet the demands, it is explained, of the many English speaking medical men in Japan. A recent issue of the *Sei-I-Kwai Medical Journal*, No. 6, volume xviii, seems to prove that Japanese physicians are engaged upon much the same subjects that interest us here and in Europe.

The Development of Stunted Minds. — The "Chicago Physiological School" has been incorporated under the laws of the State of Illinois by President Harper of the University of Chicago, and others. Work will be begun at once. The school is to be an experimental one in training children in whom development is arrested. There will be three departments—physiologic, psychologic, and pedagogic. The pupils will be kept constantly under surveillance. A close study of individual peculiarities is to be made and observations will be recorded. It is hoped thus to reach some logical conclusions concerning what environment will do for children who fail to develop normally. Owing to the closeness of the observations that are to be made, the school will receive at first only fifteen pupils.

Women in Medicine —Twenty-five years ago there were 500 women physicians practising in the United States; to-day there are 4500—or 1 to 15,000 inhabitants. Miss Elizabeth Blackwell—an American—was the first woman doctor of whom there is record. She was enrolled as a physician in the "Medical Register" of January 1, 1849. One of America's most noted women doctors, Marie E. Zakrzemska, was a native of Berlin, but she had to leave the German capital in consequence of the strong prejudice aroused against her. That was many years ago. Now the woman doctor is to be found in most European cities. In the Far East there are now women physicians, among whom the best known is a Chinese lady, Dr. Hu King Eng, first physician to the household of Li Hung Chang. Dr. Eng took her degree in the United States and is now in charge of a hospital at Foo Chow.

Danger from Turkish Tobacco.—The United States Sanitary Commissioner at Constantinople, in a recent report to Surgeon General Wyman of the United States Marine Hospital Service, says that the sanitary physician at Cavalla lays great stress upon the spread of tuberculosis among the workmen in the tobacco factories. In order to retain the qualities of Turkish tobacco, which are so much prized, it must not be exposed any more than is absolutely necessary to the air. Consequently in its manufacture into cigars no circulation of air is allowed in the work-rooms. These rooms are ill-ventilated, therefore, and damp. The workmen are crowded and obliged to breathe all the dust which the manipulation of the herb causes. They sleep in these same rooms, are badly clad and insufficiently fed. They suffer from bronchitis, expectorate wherever they can, and many of them are afflicted with tuberculosis.

Eddyism (Christian Science).—A recent number of *The Outlook* presents the following reflections upon this subject: Suppose a Mormon were to set up as a pilot, claim divine guidance, and insist on his right to take steamships in and out of New York Harbor on the strength of his proficiency in the Book of Mormon, would it be a violation of the liberty of the individual to prohibit him, and to put him in jail if he persisted? Yet the danger to the community from incompetent pilotage of an ocean steamer would not be so great as the peril from incompetent treatment of certain contagious diseases. Nor does this beg the question of assuming that Christian Science is incompetent treatment. We do not assume that it is incompetent; we assume that the community has the right to determine whether it is competent or not. Nor does this position deny the right of a Christian Scientist to go without a doctor, or even to avail himself of a mental healer. It denies the right of the mental healer to practise his mental healing as a profession for pay.

New Food for Soldiers — The *Kölnische Zeitung* of Berlin publishes an account of an experiment with a new food for soldiers called "tropon," a chemically prepared albumen product. Twenty-five officers and men volunteered for the experiment. The rations were wrapped in waterproof paper and each man received three yellow

packets containing one-day's rations of tropon rusks and tropon chocolate; also, a packet containing two-days' rations of the solid materials for tropon bean and pea soup. During three days the men, in full marching order, covered 30 kilometers each day and slept in the open air. Beer was allowed on the evening of the second day, and coffee was served on the second and third mornings. The rusks were enjoyed to the last but the men turned against the tropon chocolate toward the end of the time. The soups were made rather thick and a little salt was added. A tropon ration for three days weighs 1.200 grams, whereas the ordinary ration of solid food for the German soldier weighs 1.950 grams. The tropon ration is also cheaper in proportion to the amount of nourishment it contains.

Surgeon Huidekoper's Criticism.—Colonel R. S. Huidekoper, late lieutenant-colonel and chief-surgeon of the First Army corps and of the United States troops in Puerto Rico, read a paper "On the Organization of Army Corps" before the Association of Military Surgeons at Kansas City, Missouri, on September 29th. The colonel who had been criticised because of his management of the army camps, took occasion to defend himself and the volunteer surgeons and to attack Surgeon-General Sternberg and the regular army surgeons for the management of the hospitals at Chickamauga. "Privates, when transferred to the hospital corps as nurses were found to be drunkards, epileptics and such worthless men as were not wanted in the army." Complaints that were made were pigeon-holed. The difficulty experienced in getting medical supplies was set forth and it was declared that "the complete outfit of a brigade hospital as a unit, and the supplies for three regiments multiplied a hundred times could have been supplied by any contractor inside of two weeks." A lively discussion followed which will be printed with the meeting's proceedings after all the personalities have been eliminated.

The Yellow-Fever Situation has grown decidedly worse. From forty to fifty new cases were being reported daily at Key West at the end of last week and the beginning of this. While the epidemic is spreading in Key West itself very rapidly, thanks to the efficient sanitary measures of the Marine Hospital Service, the surrounding country is being protected. In Key West itself the disease is not very virulent in type, the death-rate being under 10 per cent. In New Orleans several new cases were reported at the beginning of the week, but no deaths from the disease. At Mississippi City, Miss., the State health officer at the end of last week announced that thirty new cases of the disease were under observation and that the disease was practically beyond control. At Jackson, Miss., the State Board of Health announced the presence of two cases of the disease on Friday of last week. While very little excitement was caused by the announcement, many of the towns in the interior of the State at once announced a quarantine against Jackson. Within a half hour, it is told, after the announcement the railroads proclaimed a quarantine. The radical measures thus taken at once, seems thus far at least, to have accomplished their purpose of confining the fever to Jackson, and the reports from the city itself seem to show that the disease is not spreading rapidly. There has been some criticism in some of the New York daily papers of inefficiency on the part of the Marine Hospital Service but it is entirely undeserved and the sanitary service meets with the warmest praise on the part of those on the scene and capable of judging of the work that is being done. It is hoped that the cold weather that occurred at the beginning of the week will aid in stamping out the disease. Key West is absolutely below the frost line, but there was frost on Sunday and Monday nights in Mississippi and Louisiana. The strictness of the quarantine being enforced against affected points may be judged from the following incident: Governor Sayers received a telegram one day at the beginning of this week from Major Scobel of the British Army, who is the United States buying mules, asking permission to come into Texas from New Orleans to secure several thousand mules. The Governor replied that he could do so by complying with the yellow-fever quarantine regulations which require him to be out eight days from New Orleans before he can enter the State. The yellow-fever situation in Havana has been very encouraging during the month of September considering especially that usually that month is expected to be the worst of the year. The report for September shows there were eighteen deaths, eight of the victims being Americans and eight Spaniards. The others were one Frenchman and one German. The total number of cases during the month was fifty-four. There are twelve cases now on hand, mostly convalescent. Surgeon Major Davis says he is well satisfied. He believes that within the next thirty days there will not be more than two or three cases. The weather is cooler and the city is clean. The Surgeon-Major considers it remarkable that Casa Blanca, formerly the worst part of the city, has had only one case of yellow fever.

The Plague Situation.—This week the center of interest in the plague has been shifted from Alexandria to Portugal again. No further cases are reported from Alexandria and there was but one death out of the three cases that developed last week. The newspaper accounts from Oporto at the end of last week were alarming enough. Confirmation has been obtained of the report that the bubonic plague has made its appearance at Baguia, a village outside the sanitary cordon. The disease was introduced there by two patients in the hospital. Later advices seem to indicate that plague has broken out among the soldiers constituting the military cordon of sanitation. Notwithstanding the evidence of the existence of the disease, some foreign sanitary officials while making the rounds of inspection of the sanitary cordon were stoned by the inhabitants of certain of the country districts and had to demand police and military protection. So much popular opposition has been aroused by the prohibition to leave the city that a decree has been signed allowing persons to leave Oporto after a medical inspection and the disinfection of their baggage; sanitary enthusiasts recommend the withdrawal of the filthy bank-notes in circulation owing to the danger of their carrying infection.

As paper money is used in Portugal for minute sums of money their number is enormous, and the measure recommended of requiring their withdrawal would be very opportune and a practical sanitary regulation. In India there is a decided improvement in the plague situation. At Poona where the disease has been raging fiercely it has unaccountably subsided. Where hundreds of cases a day were being reported up to the middle of September now there are none. Of this change and of the condition of affairs around Poona, the *British Medical Journal* for September 23, 1899, says: "Such a drop in an epidemic of plague is unknown, and it shows how much has to be learned in regard to the epidemiology of the disease. The rumor abroad in regard to the inadequacy of hospital accommodation, the paucity of doctors and nurses, and the general chaos described by certain local papers as obtaining at Poona, we are able on the best authority (Major Read, R.A.M.C.) to deny. Every European is working at high pressure, but the patients, so far from being neglected, are carefully attended to in every way. The enormity of the work may be understood when the number of plague patients is considered. Between August 1st and August 16th no fewer than 1085 cases were admitted to the plague hospitals. Of these, 154 were discharged cured, 661 died, and the remainder continued under treatment. In the districts around Poona, however, help is badly wanted." The *British Medical Journal* also announces seemingly on good authority the presence of plague in Portuguese East Africa. It adds a comment that, in the light of recent developments in the South-African situation, is of special interest: "From Lourenco Marques a telegram announces that at Magude suspicious cases of illness, believed to be plague, have occurred. The proximity of Lourenco Marques to Madagascar, and the landing of natives of Jullim at that port from Goa and elsewhere, cause this report to be viewed with considerable anxiety. Moreover, with the possibility of war breaking our in the Transvaal, and the proximity of a possible plague center so near the area of contemplated operations, it behoves the British authorities to be specially watchful of the spread of plague in this district." The report of the occurrence of plague at Assuncion in Paraquay seems to have been entirely without foundation. There has been absolute silence in the matter since the first announcement and the original despatcher of the canard seems to have selected a town from which contradiction would not come at once. One of the most encouraging recent reports from Portugal is that the Pasteur Institute Plague serum has been used there with good effect. A prominent Paris paper publishes the report of an interview with Professor Calmette, the Pasteur Institute Commissioner, who has returned from Oporto, in which the Professor says that before his arrival the mortality among those stricken with the plague amounted to thirty-three per cent. Of fifteen treated with the serum, he adds, not one died. This restored public confidence, and in three days he inoculated 423 persons.

Precautions against the Plague in Russia.—The United States Consul at Odessa, Russia, sends to the United States Marine Hospital Service an interesting and encouraging account of the steps that are being taken by the Russian Government to prevent the spread of the plague. He says: "There seems to be a general belief in this section of Europe that with the advent of the Paris Exposition the bubonic plague will be spread all over the continent of Europe, and may even reach the States of North and South America. Early during the present year an outbreak of this dreaded disease occurred in the district of Samarcand, in Central Asia. That it was brought from India there can be no doubt. It is pretty generally understood that the measures taken to stamp out and arrest the further progress of the outbreak at Samarcand were entirely successful. For reasons of public policy, I presume, no published account of the means employed was allowed to appear. The entire village was said to have been afflicted and no recoveries were reported. Troops surrounded the place and no one was allowed to enter or to leave. The village and all that it contained was destroyed by fire.

"I can recall a similar instance which occurred while I was in Central Asia in 1892. The place affected was a small Persian village in the province of Khorassan, near the Russian town of Ashabad. I was at that time reliably informed that the disease had been stamped out in the same way as I have described above. The Persian Gulf is now very seriously affected and the Mediterranean Sea also. Ten-days' quarantine is enforced here on all vessels from Alexandria, the quarantine station being at the port of Theodosia. A British ship with a general cargo arrived here recently and was given ten-days' quarantine at Theodosia, because, on her way out from England the vessel stopped at Alexandria to discharge some cargo at that port. On arrival here, after the ten days at Theodosia had been completed, the local authorities refused to allow the cargo to be discharged unless it was previously disinfected, for the reason that the ship had permitted the laborers at Alexandria to come and go quite freely while they were unloading the cargo for that place. The captain pleaded that he had not only done ten-days' quarantine at Theodosia, but had also done several days below Constantinople before he was allowed to pass the Bosphorus and enter the Black Sea. He also reminded the authorities that ten days after the exposure was the extreme limit, after which time the best sanitary authorities agreed that there was no danger to be apprehended. It was of no use, and St. Petersburg was appealed to, but the response was that the disinfection must take place. It was claimed by the authorities that the ten-days' quarantine was probably enough as far as the officers and crew were concerned, but there was danger of infection from the merchandise in the hold of the ship, on account of the laborers having had free access to the same while the ship was discharging at Alexandria.

"The Russian Government is taking strong measures to keep the plague out of the ports of the Black Sea, and Lieutenant-General P. J. Tomich has recently visited every port to inspect the sanitary arrangements of the

ports and cities, in order to acquaint himself with the requirements of the same. General Tomich is a member of the Council of the Minister of the Interior and has been specially commissioned by His Majesty to make this tour of inspection and to cause immediate steps to be taken to remove defects and improve sanitation. The General has not confined his visits to the seaport towns only, but has visited many towns inland, particularly such as have connection by water or railway with seaport towns. He not only inspects the public buildings at the places he visits, but all asylums, baths, bakeries, hospitals, boarding-houses, tea-houses, market-places, etc. Orders were given to make prompt improvements in many places which General Tomich takes care to have done, by making a second and unexpected visit to each place. The General will make Odessa his headquarters until September, and will inspect the town thoroughly and also visit numerous other places in the interior, such as Nicolaiev, Cherson, Voznesensk, Ochakov, and other towns. This visit of inspection is a matter of rejoicing for Odessa and other places as well. Our present governor, Count Schouvalov, is an extremely able man and is abreast with the times, still a special commissioner from the Emperor will have a wonderful effect in causing the authorities to move. Count Schouvalov is a reformer who has the interests of Odessa and its inhabitants at heart."

MEDICAL MATTERS IN NEW YORK.

CHARITY HOSPITALS NEED NURSES—MEDICAL DIRECTOR TRYON RETIRED—RULES FOR DISPENSARIES.

THERE are many nurses needed in the charity hospitals in this city, and the Civil Service Commission cannot furnish enough eligibles to supply the demand owing to the small number of applicants. The salary paid to the nurses desired is $300 per annum and upward. Board and lodging and instruction are furnished.

Medical Director J. Rufus Tryon, who is now sixty-four years old, has been placed on the retired list of the Navy on account of age. Dr. Tryon was for four years the Surgeon-General of the Navy. He served through the Civil War, and was with Farragut at Mobile. During the cholera epidemic in Japan in 1871 he was in charge of the United States Naval Hospital at Yokohama, and two years later had charge of the naval yellow-fever hospital at Pensacola, Fla., when there was an alarming outbreak of the disease at that place. The Venezuela Government decorated him for his services to the sick and wounded of both factions during the revolution in that country. He was the representative of the United States Navy at the International Medical Congress at Madrid just before the war with Spain. For more than a year he has been the general inspector of naval hospitals. He is a native of New York City, and he will henceforth make his home here.

The Committee of the State Board of Charities appointed to draw up rules for the government of dispensaries gave a public hearing at the United Charities Building on September 28th. The Committee consists of Dr. Stephen Smith of this city, General Simon W. Rosendale of Albany, and Dr. Enoch Vine Stoddard of Rochester. The last-named gentleman was not present. The rules as drafted by the Committee provide, in brief, that in dispensaries treating women and children at least two women shall be included in the Board of Managers; that the medical staff of dispensaries shall have two divisions, physicians and surgeons; that there shall be a registrar who shall keep a record of all cases, and investigate the ability of applicants to pay; that cases of contagious disease shall be excluded from all dispensaries, except those devoted to contagious diseases; and that there shall be a matron for each institution.

Many prominent physicians and lay trustees connected with local dispensaries were present in response to invitations to express their opinions upon the proposed rules. The rule providing for a minority representation of women on the managing boards of dispensaries was objected to for the reason that many dispensaries are under the management of incorporated institutions whose articles of incorporation would prohibit the appointment of women. On the other hand it was argued that this rule was entirely in accord with an increasingly prevalent sentiment, both in this country and abroad, that institutions treating women and children should have women members in the supervising body. The rule which attracted most attention was that which seeks to provide a means of sifting out of the vast number of applicants for gratuitous aid those who are able to pay for it. The consensus of opinion of those present was that in time there should be established a registration bureau, which should act as a sort of clearing-house, wherein should be filed a list of all applications. Doubtful cases would be investigated and their final disposition left to the respective dispensaries which reported them.

The draft of rules will probably be revised and will then be submitted for final action at a meeting of the State Board of Charities, which will be held at Albany on October 12th.

MEDICAL MATTERS IN PHILADELPHIA.

EDDYISM AGAIN—FESTIVITIES A LA HAHNEMANN—WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA—UNIVERSITY OF PENNSYLVANIA'S MEDICAL DEPARTMENT — PHILADELPHIA FREE FROM SMALLPOX—"HUGH WYNNE'S" SUCCESS—VITAL STATISTICS.

PHILADELPHIA, October 3, 1899.

THE death, from nephritis, during the past week, of an aged inmate of one of the large charitable institutions of this city, after having obstinately refused to avail herself of the medical services of the physician-in-charge, because of her reliance on the healing powers of Eddyism, has aroused the interest of the coroner, who announces that the formal post-mortem verdict in this case is a mere prelude to the developments which are expected to follow. This official, in his charge to the jury, bitterly scored the cult of the Eddyites, some of whom, he believed, had gained admission to the institution in question under the guise of visitors, and, once admitted, industriously pro-

ceeded to secure as many "converts" as possible, as it were, under the very noses of the officials. The results of these tactics has been demonstrated above, in the flat refusal of the deceased to follow the physician's directions because of her "faith" in other channels. The coroner is now undertaking an investigation in this particular case hoping to secure sufficient evidence to warrant a prosecution at the hands of the District Attorney. In view of the pernicious activity of the Eddyites and their allied sects in this vicinity of late, it is sincerely hoped that Coroner Dugan's efforts in this instance will meet with every success.

The present week has been an era of gay hilarity for the homeopaths of this State in general, and of this city in particular, the reason for their unwonted festivity having been the thirty-fifth annual meeting of the Homeopathic Medical Society of the State of Pennsylvania, held in the halls of the Homeopathic Medical College. Having been welcomed to the city with a few well-chosen words by the Mayor, the delegates of the Society at once proceeded to italicize their superior points by announcing a gratifying increase in the number of new local homeopathic medical societies through the State during the past year, and by emphasizing the fact that at present the medical staffs of certain State hospitals are becoming permeated by members of their sect. The scientific sessions were literally howling successes, and a vast array of matter was laid before the 150 enthusiastic delegates. Among the subjects of scientific interest with which the members were regaled were papers upon such topics of interest as "The Doctor's Horse, Carriage, and Stable," "The Care of the House Beautiful," "The Sanitary Use of Water," "The Doctor's Vacation," and the vital query, "Can Homeopathy Cure Malaria?"

The fifth annual session of the Woman's Medical College of Pennsylvania was inaugurated September 27th, the event being observed by holding special exercises at the institution. The opening address was delivered by Dr. Clara Marshall, the annual address to the students being delivered by the Dean of the Faculty, Dr. Emma E. Musson.

The opening exercises of the session of 1899–1900 of the Medical, Dental, and Veterinary Departments of the University of Pennsylvania occurred in the chapel of the University on October 2d. Provost Harrison and the deans of the respective departments delivered addresses to the students on this occasion. Among the important changes in the *personnel* of the Medical Faculty which have occurred since the close of the last session are the following: Dr. James Tyson becomes Professor of Theory and Practice of Medicine, as successor to the late Dr. William Pepper; Dr. Simon Flexner, late of Johns Hopkins University Medical School, succeeds Dr. John Guiteras as Professor of Pathology; Dr. John H. Musser and Dr. Alfred Stengel jointly occupy the chair of Clinical Medicine; and Dr. G. G. Davis becomes Professor of Applied Anatomy. The successor to the Chair of Gynecology, made vacant by the resignation of Dr. Charles B. Penrose, has not yet been announced, and great speculation exists as to the identity of the future occupant of this important place in the medical faculty. The competition has practically narrowed down to three of four candidates and the successful applicant for the position will probably be named during the next two or three days.

The Chief of the Bureau of Health has reported this week that this city is now entirely free from smallpox, the last case of this disease having been discharged from the Municipal Hospital a week ago. During the epidemic which prevailed last April in the near-by suburb of Nicetown, there were 111 cases, all of so mild a type, however, that none ended fatally. These cases occurred exclusively among negroes, with a very few exceptions.

The lasting impression made upon the public's mind by Dr. S. Weir Mitchell's historical novel of Philadelphia life, "Hugh Wynne," is evidenced by the unexpectedly great demand for the new Continental edition of this work now in press. This new edition is announced for publication during the coming week, but already the demand of the trade has been so large that the number of copies at first estimated as sufficient has had to be supplemented by the printing of a large second impression. This edition of Dr. Mitchell's most important novel is elaborately illustrated by full-page illustrations by Howard Pyle, by views of present scenes of places incident to the novel, and by the reproduction of many rare manuscripts and old prints.

During the week ending September 30th, a total of 364 deaths from all causes was reported in this city, or a decrease of 7 as compared with the preceding week, and of 18 compared with the corresponding period of 1898. During the week there were reported 77 new cases of diphtheria, 65 new cases of enteric fever, 50 new cases of scarlet fever, and 2 new cases of cerebrospinal meningitis.

MEDICAL MATTERS IN CHICAGO.

RELATIVE TOXICITY OF COCAIN AND EUCAIN.

CHICAGO, October 2, 1899

AT a recent meeting of the Chicago Academy of Medicine, Dr. A. H. Peck read a paper in which he drew the following conclusions with reference to the relative toxicity of cocain and eucain. (1) The action of cocain is inconstant; one never knows whether the symptoms occasioned by like quantities of the drug, in animals or individuals, under like circumstances, will be similar or dissimilar. (2) The action of eucain is constant. The symptoms occasioned by the use of like quantities in animals under like circumstances, and so far as my experiments have gone, in different individuals also, are the same. (3) The first action of cocain on the heart is that of a depressant, and on the respiration it is that of a mild stimulant, the after-effects being, on the heart, that of a decided stimulant, and on the respiration, that of a decided depressant. (4) The first action of eucain on both the heart and respiration is that of a stimulant, the after-effects being that of a decided depressant. (5) Cocain causes death in animals by paralyzing the muscles of the respiratory apparatus, the heart's action continuing in a feeble way for a brief period after breathing ceases. (6)

Eucain causes death in animals by paralyzing the muscles of the heart and of the respiratory apparatus, they ceasing to operate simultaneously. (7) Eucain in toxic doses nearly always causes nausea, and occasionally vomiting. (8) Cocain is much less nauseating and scarcely ever causes vomiting. (9) Eucain is decidedly a diuretic, causing renal discharge in a majority of instances in which a toxic dose is used. (10) Cocain is not a diuretic to any appreciable extent, renal discharge having occurred in only one instance in connection with all my experiments. (11) The pupils of the eyes, in nearly all cases of cocain poisoning, do not respond to light, and are more or less bulging from their sockets. (12) The pupils of the eyes, in most cases of eucain poisoning, do respond feebly to light, and rarely ever bulge from their sockets. (13) The action of toxic doses of eucain is more like that of a paralyzing, tetanoiding, convulsion-producing agent, than it is like an anesthetizing one, the plantar and cremasteric reflexes nearly always responding. (14) Toxic doses of cocain cause general anesthesia in connection with the other symptoms in the majority of cases. (15) True tetanus, of all striped muscles of the limbs, and Cheyne-Stokes breathing nearly always occur with the use of cocain, but seldom does either occur when eucain is used. (16) Cocain is at least three times more toxic than beta eucain, and alpha eucain is as toxic as cocain. (17) Boiling does not destroy the efficacy of cocain, but it does modify it, and boiling in no degree lessens the efficacy of eucain.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

DR. DONALD ROSS AND THE COLONIAL OFFICE — BURYING GROUNDS EXTRAORDINARY—THE GRAVELESS NAME—THE SANITARY CONGRESS AT SOUTHAMPTON — THE MUSEUM OF THE POLYCLINIC — A JUDGE'S INSULT TO THE PROFESSION.

LONDON, September 25, 1899.

THE contemptibly, insignificant part which the Government has actually played in the triumphs and advances of the English flag is again illustrated from Sierra Leone. Urgent appeals were made to the Colonial Office at the time of the starting of the Major Ross expedition to cooperate with it either in the way of funds or detailing army medical experts. This was declined as being too sudden, but hopes were held out of later assistance. As soon as the hematozoon had been found in the body of the *anopheles*, Major Ross again appealed to Secretary Chamberlain, but this time he was "not prepared." So the plucky little Liverpool School of Tropical Medicine took up the gauntlet again and sent out a permanent investigator to continue the work of the expedition. Ross' findings were even more complete than at at first reported, the proof being three fold: the presence of practically only *anopheles* in the affected barrack, the presence of the quartan parasite in three captured specimens, and its discovery in the tissues of two out of three mosquitoes permitted to suck the blood of a patient. These, with Grasse's negative experiment of taking an unacclimatized family of seven to sleep every night in the fatal Roman campagna without any ill results whatever, simply from keeping the windows of their rooms absolutely protected by perforated zinc sheets, make the "conviction" of the mosquito in general, and *anopheles* in particular, practically a demonstration, and if this species is as reported a shy breeder and quite limited in its hatching areas, the stamping out of malaria even in the tropics, seems quite among the possibilities. The value of this to England with her huge colonies and dependencies is so inestimably enormous, so palpably so to every one except an official, that really Mr. Chamberlain might let even President Kruger wait a few weeks while he attends to it. But the official intelligence is waterproofed against ideas.

It is little wonder that cremation is making headway in England. The state of affairs in some of the present city cemeteries is little short of revolting. It has of course became accepted here as a matter of course, that after the markings of a grave have disappeared and the body contained in it presumably completely decayed to a few mouldering bones that its space be used for a new interment. One can stand when a grave is being dug in any of these lonely little country churchyards, such as the immortal "Elegy" was written in, the beauty-spots of England, which almost reconcile one to death for the sake of being buried in them and having future generations come and review your ashes, and watch here a skull and there a rib brought up in the shovelfuls of rich brown earth. "Rich with the (human) spoils of time." Strangely as the gravedigger's scene in Hamlet strikes upon Transatlantic nerves its stage mountings may be seen under any Yew-tree's shade here, and Shakespeare must have been as familiar with them as with the stalls of the market-place. But about this there is nothing repulsive; Time's mellowing hand has softened the horror of death out of these relics. They have been absorbed again into the body of Mother Earth. Like the monks of Chartreuse they have had both their day and their sleep in consecrated ground—and they vanish to make room for others. But in the overcrowded cemetery of the growing city or the manufacturing town there are no such redeeming and softening features. Bones still moist and skeletons which cling together are rudely distributed and strange stories are told of gruesome sights seen by the rays of the sexton's lantern. A most painful case of this sort has just come before the courts. The superintendent of a Scotch cemetery was charged with exhuming half-decayed bodies, dismembering them, and throwing them into hollows in walks and roadways which were being filled up. Three of the gravediggers testified to having done work of this sort under his directions.

But indeed a certain amount of "shifting" is absolutely inevitable under the present state of affairs and size of cemeteries. The thing that first strikes an American about English cemeteries is their disgraceful smallness, and this is not because of the excessive dearness of land, which is actually lower than in many of our Eastern cities of similar size, but simply because our forefathers

built them that way. The wretched little boxy railway carriages, survivals of the body of a leather-hung coach, are retained on the same unanswerable ground. And to-day in the London suburbs the bodies of those who cannot afford a family lot are buried one on top of the other, five and six in a grave. A deep grave is dug and then filled up with bodies, separated by thin layers of earth, until it is full to within three feet or so of the surface, when earth is shovelled in in the usual way, at least so several eye-witnesses of the process have described it to the writer. The last body put in has the right to the headstone, and consequently this gruesomely "superior" position is much coveted by the poor for their deceased relatives It would never do to let all the names appear above, as that would shock the delicate sense of propriety of the British public, a thing no official would be guilty of, for any consideration. One has heard much of the pathos of the nameless grave, but it is certainly matched by that of the graveless name. Overcrowding and oblivion seem the lot of the poor, not only in the slums, but in God's half-acre as well.

The recent Sanitary Congress at Southampton was an admirably representative body. Some 2000 delegates were present, including 500 ladies, and nearly 200 municipalities were formally represented by aldermen, medical officers, and citizens. Dr. Newsholme of Brighton made a most favorable and well-received report upon the good results obtained under a rule of compulsory notification of phthisis. Instead of its being resented as an intrusion upon their privacy by the patient and his friends, Dr. Newsholme found in the majority of cases that they were anxious to get all the information and assistance possible from the health officer. Most of the them seemed to have got an inkling of the communicability of tuberculosis and instead of being frightened by his visit and instructions were glad to hear how to take proper precautions against its spread. This was before the conferences of medical officers of health (or "M. O. H.," as it is usually abbreviated here) and conferences of municipal representatives of port sanitary authorities and of medical officers of schools. Before this last, an excellent and timely paper was read by Dr. Shelby, urging the importance of systematic teaching of bodily hygiene to children instead of the "deliberately preserved ignorance" in which they are now brought up.

The London Polyclinic is just beginning the erection of a handsome museum-building.

The English Government is arranging to supply every military hospital in India with Calmette's antivenene.

Sir Edward Fry, late judge of what in England practically corresponds to our Supreme Court, has written a letter to the *Times* in which he repeats the absurd and baseless allegations of the London Chamber of Commerce as to the receiving of commissions by medical men from druggists, mineral-water companies, and undertakers. He has no new proof whatever, but simply repeats second-hand gossip from certain druggists and opticians, who, naturally, "did not wish their names to be mentioned." His insane and diseased imagination actually carries him to the insulting length of picturing a doctor watching beside the bedside of a patient hovering between life and death, and debating whether he had better cure him or let him die and get the undertaker's fat commission!! The man who commits such delirium-tremens conceptions as this to paper simply writes himself down as little better than an idiot, and his spiteful insult is beneath contempt. It is simply a survival of the old, vulgar, superstitious dread and distrust of doctors which abounds among slum-dwellers and darkeys, but which we hardly expect to find among civilized and intelligent people, let alone justices of the Supreme Court.

SOCIETY PROCEEDINGS

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held September 28, 1899.

THE President, DR. S. O. VANDER POEL, in the Chair.

After the nomination of officers for the ensuing year had been made, DR. WILLIAM H. PORTER read a paper, entitled

HOW NATURE UTILIZES THE IRON CONTAINED IN THE BLAUD PILL.

Dr. Porter said: A discussion of the use of iron in anemia, and especially in the popular form of the Blaud pill, may seem needless, yet there is by no means a perfect agreement as to its indications, and the method in which the iron acts is so much a matter of dispute that the whole subject merits careful review. The fact of the matter is that the physiologic action of iron in anemia is not well understood. To understand it we must know how hemoglobin is formed for the blood and how it is destroyed. Neither manganese nor iron, even in cases in which they act beneficially in relieving anemia, are directly absorbed. It is a very wise provision of Nature that these substances are not absorbed, and they seem to be kept out of the system by the same mechanism that keeps other toxic substances that may be in the intestinal tract from absorption into the circulation.

In considering the formation of hemoglobin, it must be remembered that while plants have the power of synthesis, that is, of building up more complex compounds out of simple ones during the course of their nutrition and growth, animals have not. Animals live by analysis; that is, by breaking up complex substances into simpler ones. If this cardinal principle in the biology of the two forms of living things, for it is an essential distinction between their modes of existence, be borne in mind, the mistake will not be made of thinking that the absorption of inorganic compounds into the system takes place or that they are used in it. Hemoglobin is not thus formed. Its great source is the nucleo-albumen of plants. This is a very complex substance contained in many vegetables, especially the green plants. It has a very complex chemical formula, and is polymeric in a high degree. It resembles globulin, but is distinguished from it by the presence of iron and phosphorus, which do not occur in the globulin of animal tissues and fluids.

Now the nucleo-albumen occurs also in animals, but in them this substance is much less complex and is monomeric. The nucleo-albumen of the plant has undergone a change during the process of absorption and metabolism with the production of a certain amount of energy.

A possible anabolic process in the body involving nucleo-albumen is its conversion into hemoglobin and lecithin or similiar compounds. Lecithin becomes a nerve food or is perhaps a nerve stimulant. The explanation of the formation of hemoglobin and the destination of the plant nucleo albumen consumed would thus be possible without having recourse to any of the somewhat far-fetched theoretic considerations that are often appealed to in the discussion of this subject.

Animal nucleo-albumen is more easily digestible and is thus more economic. It very probably supplies its properties to the tissues after absorption more readily than plant nucleo-albumen, but it is a less valuable product for metabolism because capable of undergoing less change and incapable of furnishing all the energy that such chemical changes bring into play. The consumption of larger amounts than the system bears well is necessary in order to keep up the balance of supply and demand in the tissues. Hence, the anemia that often develops in nursing children if they are kept too exclusively on the breast, or in other children if they are limited to a milk diet as they grow older, for in this case they are taking in only animal nucleo-albumen. Hence, too, the necessity for supplying children with vegetable products as soon as they are able to digest them.

In all cases the best results as far as blood making, especially hemoglobin formation, is concerned are secured by a proper mixture of the two kinds of food, animal and vegetable. A proper adjustment of these two classes of diet must be made, especially for anemic people and this is much more important than any other therapeutic measures. It must be remembered that no matter what the form of iron given medicinally the iron absorbed for blood-making purposes all comes from nucleo-albumen.

Now anemia may result either from too free an escape of hemoglobin or from insufficient provision of nucleo-albumen. The first occurs in hemorrhage and is a surgical condition; the second is medical anemia so to speak. This latter form of anemia may be due, first, to an insufficient ingestion of nucleo-albumen, second to insufficient absorption of nucleo-albumen, the sulphur compounds in the intestine uniting with it and making it impossible of absorption; and third, may be due to internal organic disturbance so that the nucleo-albumen though absorbed is not properly used up in metabolic processes. This happens in infectious diseases when, because of the presence of inhibitory conditions organs do not functionate properly, or in liver or renal diseases when toxins are either thrown into the circulation, or are retained when they should be excreted.

For the first form of anemia, that from insufficient ingestion of nucleo-albumen, more food should be taken, and not only the quantity, but also the quality of the food as regards its contents in hemoglobin-forming substances should be regulated. Besides, the digestion and the nervous tone should be improved as much as possible. To give iron in these cases unless there are sulphur compounds present in the intestinal tract which are disturbing the absorption of the hemoglobin-forming material, is apt to be worse than useless, perhaps positively harmful.

In the second case, when sulphur compounds are present, sufficient iron must be given to satisfy these so that the nucleo-albumen and its contained iron may escape their action. For this purpose any, not too stable, iron compound will do. It is not absorbed. Any iron compound that is used will, in its passage through the stomach, be changed into the chlorid of iron. Even the iron albuminates that have been so much lauded of late years are not absorbed. They are not true compounds, but are mixtures of certain loosely combined iron salts with albuminous material. They too are changed into the chlorid in passing through the stomach. It is a saving of energy, therefore, to give the chlorid of iron directly since it alone needs to undergo no change in the system. The chlorid, however, sometimes acts as an irritant to the digestive tract, and then other and less irritating iron compounds may be employed.

Among the most popular of the other forms of iron is Blaud's pill. It is usually tolerated very well, and when fresh is readily converted into the chlorid of iron. It is to be remembered, however, that its use always involves a certain expenditure of digestive energy and uses up a certain amount of hydrochloric acid for its conversion. This warning applies to every other iron compound, whether organic or inorganic, officinal or unofficinal.

A concentrated nucleo-albumen is the best form in which to administer iron compounds. Hemaboloids is a concentrated solution of vegetable nucleo-albumen. This serves the purpose of neutralizing or satisfying the iron compounds in the intestine, and at the same time supplying the natural form for absorption.

It serves excellently the purpose of preventing the destruction of other nucleo-albumens in the digestive tract by the sulphur compounds, for other forms of iron are sometimes slow to act, and the nucleo-albumen is destroyed before they succeed in taking up the sulphur compounds present. This does not happen with hemaboloids. This use of Nature's own method of supplying iron by giving it as a nucleo-albumen is a distinct step forward in iron-therapy. It lifts the subject from the hazy domain of empiricism into the realms of rational therapeutics.

In discussion Dr. Stoll said that for most physicians the administration of iron is mainly empiric but that studies like Dr. Porters' give promise of raising it to the highest plane of rational therapeutics. While the tincture of the chlorid of iron has always seemed to be of most benefit to patients suffering from Bright's disease or from loss of albumen because of albuminuria in general hemaboloids have proved the most useful form of iron. It is of benefit in a greater proportionate number of cases of anemia from all causes than any other form of iron medication. Especially does it seem to do good in cases of chlorosis in which neither the chlorid of iron nor Blaud's pills are effective. One of the disadvantages of Blaud's

pills that is not borne in mind sufficiently, is their liability to be furnished by the pharmacist when not fresh. Old pills of any kind are apt to be inefficient, but of Blaud's pills this is especially true. Perhaps if we could always be sure of a recent preparation there would not be so much to find fault with in the old favorite prescriptions of iron. It is in this respect that hemaboloids is of advantage; it does not seem to deteriorate when kept for a time.

In closing the discussion DR. PORTER said that this matter of the freshness of Blaud's pills when used is extremely important. Old pills have their chemism completely satisfied and they do not take up the sulphur compounds in the intestinal tract and so fail entirely of their purpose.

DR. CARL BECK then read a paper on

SOME IMPORTANT POINTS REGARDING THE PERFECTION OF ASEPSIS.

He said in brief: Asepsis is not a function of the use of strong chemicals, though any number of lively drugs have of late years been vaunted for the purpose; it is rather the result of the most scrupulous care in cleanliness. Instruments, ligatures, and all the cloth material that is liable to come in contact with the patient may now be sterilized perfectly. Certain other things still remain in which to secure asepsis, and this is a more difficult matter. Of these the atmosphere claims attention first. It used to be considered the great carrier of infection. We now know that it is seldom the source of the septic material in a case where infection takes place. Any number of micro organisms exist in the air, but by far the vast majority of them are not pathogenic and many of those that are pathogenic exist under forms that are not very virulent.

Pathogenic micro-organisms that get into the air settle to the floor. It has been shown that the heavier bacteria settle in an hour, the lighter forms in two to three hours. Hence there should be no disturbance of the dust in an operating-room for several hours before an operation. It is advisable also to have the air of the operating-room saturated with moisture, for then microbes do not float in the air. This may be accomplished by having a kettle steaming in the room for several hours before the operation.

The air expired by the healthy surgeon in quiet expiration contains as a rule practically no bacteria. If the surgeon has a tonsillitis or a rhinitis his breath is not free from bacteria. If he talks or coughs bacteria are projected into the air, sometimes in considerable numbers. During an operation the old proverb, "Speech is silver, silence is golden," is especially true. Assistants at an operation should so know their business so well that they can anticipate the wants of the surgeon, or are able to understand the slightest sign. They should not need to be spoken to. Bacteria in the skin of the patient and surgeon may be removed by patient scrubbing with soap and water. Alcohol should be freely used in the cleansing process because it removes the grease, which is a favorite abiding place for the bacteria. It is probable that strong antiseptics, such as lysol and bichlorid really do very little good. The trouble in cutaneous asepsis, however, is that the bacteria collect below the surface of the skin in the various cutaneous glands. These cannot be removed. Even pyogenic bacteria may be harbored here, and they are a fruitful cause of stitch abscesses and the like. They may cause suppuration in a wound that has been made with the most careful attention to the minutiæ of asepsis.

These microbes cannot be got rid of directly, but the dangers they may give rise to can be avoided. The knife with which the skin incision is made should be changed, and the hands washed immediately after the skin incision is completed. If gloves are worn they should also be changed. After the operation the incision should be brought together by subcutaneous sutures, the skin edges being coaptated last of all. If sutures for the relief of tension are a necessity they should be inserted from three-fourths to one inch from the line of incision.

As to the hands of the surgeon, as no incision is made beneath the surface of the skin, carefully washing will suffice. If much force is used in manipulation the hands should be washed afterward lest pathogenic bacteria should have been squeezed out of the gland crypts. If the operation lasts long the hands should be washed several times.

Of course in the matter of infection predisposition plays an important rôle. Some constitutions are able to effectually dispose of considerable infective material without the slightest inconvenience resulting to the individual. No rules for the prevention of a predisposition to infection can be formulated and the surgeon must therefore be careful at every point. Rubber gloves during an operation are a help in maintaining asepsis and should be employed. Especially are they of service when the surgeon's fingers must be put into places that swarm with bacteria, as the rectum, or in manipulations in abscess or other septic cases. How much simple cleanliness can accomplish in warding off infection is evidenced by the life work of the late Lawson Tait. Manipulations that require much force should be carried out instrumentally. Forceps, for instance, should be employed in tying sutures, and a needle-holder rather than the fingers in forcing a needle through the tissues.

It must not be forgotten that manipulative skill still counts for much in preserving the patient from opportunities of infection. Any one who saw Langenbeck operate in the preaseptic days and followed his cases in order to note the results he obtained, would realize how much this skill in surgical manipulation availed in his hands. The short duration of the operation, the gentle handling of the tissues, the sharpness and perfection of his instruments, counterbalanced in a way the shortcomings of his asepsis. He was able, as a consequence to do some exquisite and very successful plastic surgery. This faculty of skilful surgical manipulation must be carefully cultivated now, too, by any one who would do ideally successful surgical work.

In the discussion which followed DR. GARRIGUES said that Dr. Beck's suggestion as to the way to get around the bacteria in the lower layers of the skin is a most in-

genious one, and comes in the manner of a revelation. It is the Columbus'-egg expedient of a difficult problem. We cannot get at these deeply situated bacteria, and the suggestion to use a second knife for all incisions beneath the skin is most promising and suggestive.

The danger he suggested from the bacteria contained in the mouth if the surgeon should talk is no merely theoretic scarehead, but a very real peril. It has been noted experimentally that during moderately loud speech bacteria may be projected several yards from the mouth. Alcohol is fortunately regaining the place that it used to hold as an antiseptic. A good while ago it was thought much of, and then its use was given up for a time. Ahlfeld, in the last edition of his "Treatise on Obstetrics," says that it is the most efficient of antiseptics, while being absolutely harmless. Used in ninety-five per cent. strength it will destroy any of the ordinary pathogenic bacteria in a very short time. For skin disinfection it is best used on strips of flannel. Surgical dexterity is undoubtedly of the greatest service in lessening mortality both because of lessened danger from infection and because the patient is submitted to less actual risks during the operation. Another important factor in reducing operative mortality is skill in anesthetizing. The presence of visitors at operations always increases the risks and it is good that Dr. Beck calls attention so forcibly to it once more.

In closing the discussion Dr. Beck said that it seems to have been proven that fifty per cent. alcohol is quite as effective as a germicide, as is ninety-five per cent. alcohol. The difference in price would make quite an item in hospital expenditures. Alcohol is mainly useful in removing grease to which bacteria persistently cling. Visitors are dangerous at an operation, not because of the bacteria their breathing may scatter around, but because of the liability ever present that they may come in contact with towels and other things afterward to be handled by the surgeon, or be used on the patient. Gentle exhalations contain practically no bacteria of surgical importance.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Abstract of the Proceedings of the Twelfth Annual Meeting, Held at Indianapolis, Indiana, September 19, 20, and 21, 1899.

(Continued from page 448.)

Second Day—September 20th.

The President, Dr. Edward J. Ill of Newark, N. J., in the Chair.

Dr. Walter B. Dorsett of St. Louis, Mo., read a paper, entitled

Shall we abandon ventrofixation of the uterus?

The essayist had performed thirty-eight ventrofixations. Four of the patients have borne children without any of the usual troubles reported in pregnancy or during the delivery of the child. Eight of the operations were performed to correct different degrees of prolapsus, and the remainder were for retroflexion and retroversion.

Dr. X. O. Werder of Pittsburg reported

Five cases of firm ventrofixation followed by delivery at term.

In two cases dystocia followed the operation which was performed for complete prolapse of the uterus with inversion of the vagina. One case terminated spontaneously, the other patient required Cæsarian section. In both cases a number of operations were performed at one sitting, including curettement, amputation of the cervix, anterior colporrhaphy, ventrofixation, and perineorrhaphy.

Dr. H. W. Longyear of Detroit presented a paper, entitled

A simple, effective, and esthetic operation for shortening the round ligaments.

The operation was first brought to his attention in 1897 by Dr. J. H. Kellogg.

1. The incision is made about an inch in length, somewhat shorter in thin subjects, parallel with and just above Poupart's ligament, and with its outer end about half an inch inside the internal ring. It should pass through skin, superficial fascia, and fat down to but not including the loose tissue which overlies the tendon of the external oblique. An incision of this length and situated as directed will be practically bloodless. If begun too far back, a branch of the superficial epigastric artery may be severed, and if too far forward, a branch of the superficial external pudic artery will be encountered, while if carried beyond the layer of fat, veins will be cut which will cause the field of operation to be more or less obscured. The location of the internal ring is determined by the pulsation of the femoral artery which passes just under it.

2. The separation of the wound transversely by the use of eye-retractors mounted on long handles.

3. Clearing away the loose tissue overlying the tendon of the external oblique by pulling it from side to side longitudinally with the wound with blunt hooks, and catching with the retractors each successive layer as it is raised up by the hooks. The blood-vessels in this tissue are thus pulled back and held out of the field of operation. With the retractors holding back the tissues a field of about one inch square in size is presented, with the smooth white, glistening aponeurosis forming the tendon of the external oblique, at the bottom. Its oblique fibers can be usually easily traced to their junction with Poupart's ligament. By moving the retractors in various directions, being careful at the same time to keep the tissues within their grasp, a much wider field may be inspected, if necessary.

4. Puncture, one-quarter of an inch in length, of the tendon of the external oblique, with the scalpel, at a point just above Poupart's ligament, and at the outer aspect of the cleared space.

5. Insertion of the blunt hook, which should be passed downward close to the floor of the inguinal canal, then inward and upward, and the ligament with its surrounding investment of fat will be brought up out through the opening in the tendon.

6. Isolation and pulling out of the ligament, which is facilitated by stripping back the adipose and cellular tis-

sue with blunt-pointed forceps as it emerges through the opening, and, if necessary, cutting with scissors any tendinous attachments which impede its freedom. Care should be preserved during this maneuver not to cut the cuff-like prolongation of peritoneum which forms the canal of Nuck, and which is usually dragged from the internal ring, and makes its appearance as the ligament nears the uterus. If the ligament still comes out easily, its attachments can be carefully snipped with the scissors and the cuff rolled back.

7. The anchoring of the ligament is done by means of silkworm-gut or kangaroo-tendon sutures which are passed from the skin surface, and which also serve to close the wound, although superficial catgut sutures for the latter purpose are also used. The loop of ligament, which will be from two to four inches in length, is held up by the assistant while its proximal portion, as it emerges through the opening in the tendon, is made fast to this structure by the suture which is passed first through the aponeurosis, then the ligament, so as to grasp about two-thirds of it, and then the aponeurosis on the opposite side, and left untied. An aneurism needle is now passed in and out through the aponeurosis of the inner aspect of the wound, and through these two opening the loop of ligament is drawn by means of a heavy silk thread, turned backward upon itself and made fast to the aponeurosis and ligament by passing the loose suture through both sections and tying. The one strand of kangaroo tendon or silkworm-gut is thus made to pass through the ligament three times and fasten the bunch together to the aponeurosis, in which position Nature will soon make permanent fixation.

8. The wound is closed with fine catgut, using the buttonhole stitch, after which the wound is sealed with iodoform collodion, reinforced with a layer of gauze, which is saturated with the collodion, thus making a firm and impervious seal. Before using the collodion, the surface of the skin where it is to be applied should be bathed with sulphuric ether, which removes any oily material, and thus insures the firm adhesion of the seal. A thick pad of gauze and a T-bandage completes the dressing. The seal is removed after the tenth day, and as it is stripped off, the catgut sutures, which by that time are absorbed beneath the surface, come away with it. The time required by this method of operating is very much less than by the Alexander method.

Previous to operation a suitable pessary should be fitted for holding the uterus in anteversion during the operation, and this should be left in position with occasional inspection for three months afterward.

Dr. Charles A. L. Reed of Cincinnati then delivered the memorial address on Lawson Tait, the great Scotch surgeon of Birmingham, England, who died at Llandudno, Wales, June 13, 1899, and who was an honorary member of the Association.

The President's Address was delivered by Dr. Edward J. Ill of Newark, N. J. He selected for his subject

THE RIGHTS OF THE UNBORN; THE PREVENTION OF CONCEPTION.

He said an abuse, fostered by the security that aseptic surgery gives us, has gradually crept into the work of many physicians all over the civilized world. The rights of the unborn are often not respected as they should be and as a strict regard for truth, conscientiousness, and careful professional thought on our part would indicate. The rights of the unborn would be more respected if it could secure for itself competent legal authority to represent it before a court of law.

The induction of abortion is performed too frequently; the law and custom of consultation leave a wide field for opinion, judgment, and professional courtesy. Too frequently the practitioner's sympathy runs away with his reason. The frequent deaths of the unborn as caused by the regular profession legitimately must ever remain a sign of weakness and impotence of an otherwise noble and humane profession. The indication for such an operation must greatly change with the advance of therapeutics. Before long we shall be told that the life of the fetus must not be taxed less than that of the mother. When that becomes an axiom our resources will increase to an astonishing extent. Changes in that direction have been very apparent during the past few years.

RETROPERITONEAL TUMORS, WITH REPORT OF A CASE AND PRESENTATION OF SPECIMEN.

Dr. Rufus B. Hall of Cincinnati read a paper on this subject, in which he said that retroperitoneal tumors that are operable are rare. His experience in dealing with them as far as the removal of the tumor is concerned has been limited. All retroperitoneal tumors are difficult to remove and the operation is attended by a high mortality. They are often malignant.

Dr. James F. W. Ross of Toronto read a paper, entitled

RUPTURE OF THE PUERPERAL UTERUS, WITH REPORT OF CASES.

The essayist said that it is well known that rupture of the uterus might occur before or during labor. To diagnosticate a rupture of the uterus before labor is extremely difficult. It is a subject about which very little is known. The cases under discussion were not those before labor, but those occurring at the time of labor. Every practitioner should be familiar with the symptoms of this condition so as to be able to recognize it at as early a date after its occurrence as possible. He then mentioned the different causes of rupture of the uterus that are well known. He stated that the question as to whether rupture of the uterus occurs more frequently in the first or in subsequent labors is still one that has not settled. Some authorities claim that rupture is more frequently met with in primiparæ than in multiparæ; others claim it is more frequently met with in multiparæ than in primiparæ. Some state that rupture of the uterus may take place before the membranes have been ruptured. He considers that the duration of labor has a great deal to do with the production of rupture of the uterus as the organ seems more prone to tear after its structure has become impaired by continual and prolonged contraction. The fundus is less frequently ruptured than the body, and the body less frequently ruptured than the cervix.

The posterior wall of the lower segment seems to be the commonest site of rupture and the tear is generally found to run toward the left. These tears usually extend over a distance of three or more inches. He considers that cases of rupture of the uterus might be divided into four groups: first, those which are beyond hope from the beginning, in which the patients have the usual classical symptoms of rapid pulse, dyspnea, precordial uneasiness, nausea, vomiting, and cold perspiration. Second, those cases which, owing to delay, have passed beyond the operable stage, the patients having become ill with commencing septicemia and peritonitis, the peritonitis and septicemia drawing attention to the case, and this extra attention revealing the fact that rupture of the uterus has been present without giving rise to early symptoms to indicate its existence. Third, a class of cases in which rupture is not immediately fatal, in which it is early recognized, and in which the patient is in good condition for operative interference. Fourth, a class of cases in which rupture is never recognized, but in which septic symptoms develop without any evident reason. In a case in which a very rapid pulse follows a fairly severe labor and peritonitis sets in, rupture of the uterus must be considered when endeavoring to discover the cause of the abnormal course of the puerperium.

Intraperitoneal hemorrhage can be diagnosticated by percussion in the loins. The essayist stated that he had diagnosticated intraperitoneal hemorrhage in this way on several occasions. The percussion sound may change as a consequence of the changed position of the clot, and when it does change it does so slowly.

In summing up the treatment of these cases he said that it is necessary to treat them according to the class to which they belong. In the first class the patient is practically moribund before the physician in charge can call counsel. In the second class of cases, in which there are no symptoms to indicate that rupture of the uterus has occurred, the treatment must vary from that carried out in the third class. The treatment in the second class is that indicated in the cases reported, namely, thorough drainage and thorough cleansing from below. He considered that an abdominal operation under such circumstances would be unfavorable and injurious to the patient. Already adhesions have formed to protect the general peritoneal cavity, and these must of necessity be broken down and increase the risk. In the third class of cases, in which rupture is recognized, in which the patient is not moribund from shock and hemorrhage, there can be but one line of procedure to carry out, namely, celiotomy, thorough inspection of the parts, removal of blood-clot from among the intestines, thorough stoppage of hemorrhage from the wound either by approximating sutures or gauze packing, and the establishment of thorough vaginal or abdominal drainage, or both. In the opinion of the essayist, suturing the rent is scarcely called for, as by this procedure the operation is unnecessarily prolonged, and the length of time consumed by such an operation is of importance. Any one who has had experience with this tragedy of the lying-in ward must have noticed that the edges are so bruised as scarcely to hold a suture. To pare them off means increased hemorrhage and increased delay. He prefers packing with gauze, and is satisfied that the uterus afterward becomes perfectly normal. Hysterectomy under such circumstances must prolong the operation, increase the shock, and unsex the patient.

WOUNDS OF THE LIVER AND BILIARY TRACT.

Dr. W. E. B. Davis of Birmingham, Ala., read an interesting paper on this subject, in which he said that penetrating wounds of the liver are not common. The surgeon may inflict such injuries in the treatment of hydatid cysts and abscesses of the liver. Severe wounds usually prove fatal. There is often injury to the biliary canals of the liver, and the extravasation of bile contributes to the fatal issue. He reported three cases illustrating injuries produced by the surgeon.

He also reported the case of a woman, sixty years of age, whose symptoms indicated obstruction of the common duct. The liver extended almost to the umbilicus. No nodules were to be made out on the surface. There being no obstruction in the common duct, it was decided that the obstruction was in the hepatic duct or its branches. A free incision was made into the right lobe of the liver with the hope of opening some of the biliary canals and thus relieving cholemia. Death occurred a few days after from exhaustion. The patient was almost in a dying condition at the time of the operation. A large malignant nodule was found at the autopsy in the transverse fissure, which completely obstructed the branches of the hepatic duct.

Third Day—September 21st.

Dr. John Milton Duff of Pittsburg contributed a paper on

HEMORRHAGE AND THE MENOPAUSE.

The essayist does not believe that hemorrhage is a necessary concomitant of the menopause. When it does occur other than as a metrorrhagia in the true sense of that term, it is in ninety-five per cent. of the cases significant of a pathological condition. During the past three years he has interrogated 482 healthy women over fifty-two years of age. Of these only 39 gave a history of what could be termed a hemorrhage during the menopause, and out of this number only 5 gave a history of hemorrhage of any persistency. In 187 tabulated cases, of women between forty three and fifty years of age, suffering from uterine hemorrhage, 19 were due to pregnancy, 48 to malignant disease, 53 to fibroids, or uterine cysts, 10 to diseased endometrium, 26 to diseased appendages, while in 31 no positive diagnosis was made. In view of such statistics the author fails to see how any physician can argue, as he had heard them do, that hemorrhage during the menopause is not as a rule significant of disease.

REPORT OF FOUR ADDITIONAL CASES OF UTERINE FIBROIDS COMPLICATING PREGNANCY.

This was the title of a paper by Dr. M. Rosenwasser of Cleveland, Ohio. The report formed the basis of a discussion of the subject under the following headings:

I. Before delivery. (*a*) In the interest of mother and child. (1) Non-intervention; (2) myomectomy; (3) Porro operation; (4) vaginal Cæsarian section. (*b*) In the interest of the mother. (1) Induction of abortion; (2) hysterectomy.

II. After delivery. (*a*) Non-intervention. (*b*) Hysterectomy, indicated by recurrent hemorrhage, and septic infection.

Non-intervention is recommended whenever, on account of its location, the tumor does not interfere with delivery, or when its moderate growth will admit of delay until viability of the child. Myomectomy for pedunculated fibroids is a safe procedure; but the enucleation of fibroids before viability risks the life of the child, as abortions are frequent. After viability it is indicated when it is desirable and possible to preserve the uterus, or during labor when a myoma of the cervix obstructs the pelvis and cannot be dislodged. The Porro operation is the safest procedure after viability of the child, or at term if the tumor obstructs delivery and if the uterus must be sacrificed. Vaginal Cæsarian section, as proposed by Dührssen, has not yet been tried. Induction of abortion is considered more dangerous and less readily controllable than hysterectomy. Distress from abdominal distention or pressure, interference with vital functions, or great and constant anxiety may require hysterectomy as an emergency operation. When the tumor is located in the lower segment of the uterus, or in the anterior lip of the cervix, or in the broad ligament, and encroaches on the pelvic space so as to constitute a barrier to delivery, the patient is entitled to her choice of time of intervention, whether before or after viability of the child

After safe delivery only distinct indications warrant any intervention. Post-partum hemorrhage and sepsis should be managed the same as though no tumor were present. Hysterectomy becomes necessary during the puerperium when the hemorrhage cannot be permanently checked, or before infection or sloughing of the myomatous uterus, or the retention of the secundines has led to general acute septicemia.

DR. J. HENRY CARSTENS of Detroit read a paper on

THE TECHNIC OF ABDOMINAL HYSTERECTOMY,

and was followed by DR. CHARLES STOVER of Amsterdam, N. Y., who contributed one on

THE TREATMENT OF INERTIA AND SUBINVOLUTION.

The practice of discharging puerperal patients after the third day, with the direction that if anything goes wrong the doctor is to be recalled, deprives the lying-in woman of an opportunity for the detection of subinvolution. The stasis of the circulation and absence of muscular contraction lead to metritis, endometritis, retroflexion and prolapsus. Muscular contraction may be secured by the physician at all stages of labor to overcome inertion and during convalescence to prevent subinvolution. In the treatment of inertia during the first stage of labor, ergot is to be condemned, and rest secured by sleep. In the second stage, instrumental delivery will usually be indicated, but the slowly interrupted faradic electrical current is useful, selecting the primary current when the secondary may be painful. Strychnin is to be given in doses of $\frac{1}{20}$ to $\frac{1}{40}$ of a grain, repeated in two hours if necessary. Ergot is not advised save in exceptional cases, and then in doses of 5 minims every fifteen or thirty minutes. In the third stage, when post-partum hemorrhage may have complicated the situation, after coagula have been turned out and secundines removed beyond doubt the faradic current is of great value. It may be applied with one pole over the abdomen, and one at the lumbar spine. This is usually sufficient, but the intra-uterine bipolar application may accentuate its efficiency. The telescopic electrode invites sepsis. Ergot should be given hypodermatically. Manual compression and massage should not cease for an instant. The treatment of subinvolution presupposes the exclusion of endometritis, fibroids, retained secundines or any pathological state, the condition being distinguished by stasis and muscular inaction. The interrupted faradic or galvanic current is to be used daily. Hot-water douches, as outlined by Emmet, are of value. Boroglycerid tampons, daily or every other day, are likewise helpful by depleting the tissues. Ergot is still of use, particularly in sthenic and rheumatic subjects when combined with the citrate of potassium as used by Lawson Tait, in doses of ½ dram to 1 dram in half a pint of water four times daily an hour before meals and at bedtime.

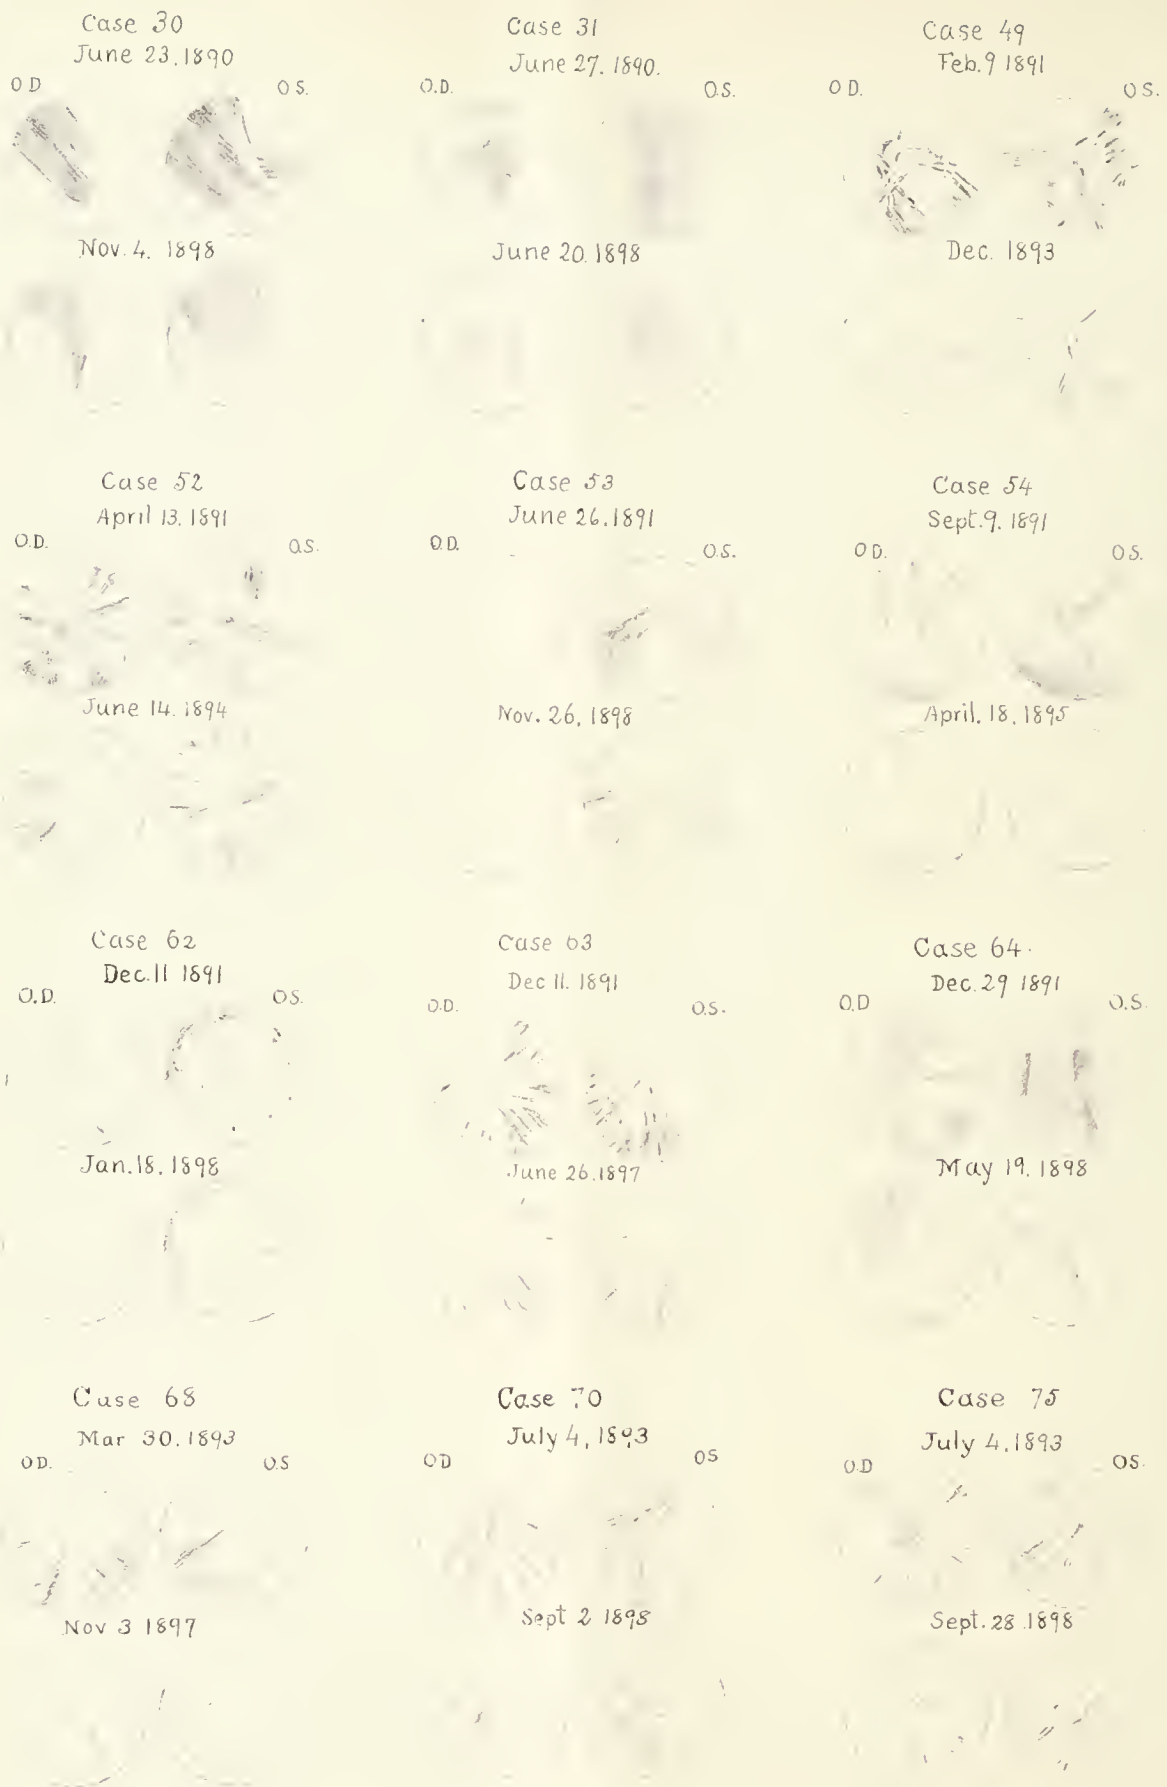
CHOICE OF METHOD FOR TOTAL HYSTERECTOMY, AND SOME POINTS OF TECHINC

was the title of a paper contributed by DR. B. SHERWOOD-DUNN of Boston, Mass., in which he compared the abdominal operations of Richelot, Le Bec, Doyen, and Martin, with the American method, much to the favor of the last named, and emphasized the advantages of the preservation of the cervix by giving five reasons in its favor: First, prolonging of operation because of hemorrhage from the lateral and posterior vaginal arteries and closing of vaginal opening. Second, danger to the ureters. Third, in some women the os and cervix are the seat of sexual pleasure. Fourth, the cervix forms an integral part of the pelvic floor. Fifth, the opening into the vagina increases the chances of infection.

INTRAPELVIC ADHESIONS.

This paper was contributed by DR. WALTER B. CHASE of Brooklyn, N. Y. Any surgeon of experience can recall not a few cases in which adhesions were the principal factors of trouble, often only relieved on opening the pelvic cavity. The symptoms sometimes are apparently out of all proportion to the gravity of the conditions existing. We have encouragement in the future in the use of Dr. Skene's electrohemostatic method. To prevent the formation of new adhesions, leave as little raw surface as possible, use absorbable ligatures, and wash with normal salt solution what raw surface cannot be covered.

The following officers were elected for the ensuing year: President, Rufus B. Hall, Cincinnati; first vice-president, L. D. Dunning, Indianapolis; second vice-president, T. J. Crofford, Memphis; secretary, William Warren Potter, Buffalo; treasurer, X. O. Werder, Pittsburg. Place of next meeting, Louisville, Kentucky, 1900.



Lenticular opacities before and after treatment by conjoined manipulation and instillation. (Kalish.)

THE MEDICAL NEWS.

ORIGINAL ARTICLES.

THE ABSORPTION OF UNCOMPLICATED IMMATURE CATARACT BY CONJOINED MANIPULATION AND INSTILLATION.[1]

BY RICHARD KALISH, M.D.,
OF NEW YORK;
OPHTHALMIC SURGEON TO THE CITY HOSPITAL; CONSULTING OPHTHALMIC SURGEON TO THE BOARD OF HEALTH AND TO THE J. HOOD WRIGHT MEMORIAL HOSPITAL.

NINE years ago my first paper on this subject was read at a meeting of the Section on Ophthalmology of the New York Academy of Medicine, and a few months later my second paper was presented at the annual meeting of the County Medical Society. These papers were hurriedly prepared to forestall the publication, in a religious weekly, of a description of this new method of treating cataract. The presentation of these papers, and their almost immediate publication in the *Medical Record* put a quietus on the mistaken zeal of these patients and the announcement to the profession was thus made through the regular channel of communication. Although this announcement was so prematurely made, the widespread interest it aroused and the active investigation it provoked demonstrated how great was the need of some method of treatment that would arrest the progress of immature cataract. Since that preliminary report was made a sufficient period has elapsed to practically demonstrate the permanency of the results obtained from the treatment then advocated, and to determine the varieties of immature cataract that will respond favorably to the treatment.

Certain important considerations must be referred to and explained in order that the scope of this report be clearly understood. As uncomplicated cataract I define all cases unaccompanied by systemic or local disease, and as illustrative types of the former I would instance, diabetes, nephritis, etc., while as local pathologic change I would mention keratitis, retinitis, etc.; but as to whether arthritis—rheumatic or gouty—be a complication, I am not prepared to state and must leave this matter for the present, *sub judice*. An error of refraction is an accompaniment, not a complication.

The extraction or absorption of cataract has a single object in view: the restoration of vision to as great a degree of usefulness as it is possible to obtain. Therefore, in mature cataract, if light projection be faulty an operation is advised only in cases of complete blindness, when even an imperfect result will give a more serviceable eye than would the retention of the opaque lens with its accompanying blindness. So in the absorption of cataract, the treatment is never undertaken except there be an absence of concomitant local or constitutional troubles. The reason is obvious, as good and useful sight could not be obtained. This is established by the following observations:

CASE I.—The patient was referred to me from a neighboring city, with a history of commencing cataract treated by his physician for more than a month by my method. The lens opacities had cleared markedly, but only a slight improvement in vision had been obtained. Ophthalmoscopic examination revealed an extensive albuminuric retinitis, with consecutive atrophic condition of the optic nerves. The diagnosis of nephritis was corroborated by a general examination. Uremic symptoms followed and death, in uremic coma, supervened about two and one-half years after my first examination. Three months before his death ophthalmoscopic examination of the lens failed to disclose any advance of the cataractous process.

CASE II.—This occurred in a very robust and muscular man, aged fifty-four years. There was a general haziness of both lenses, with denser streaks running from the edge to almost the center of the lens. It was impossible to obtain a view of the deeper structures; but after a treatment lasting about six weeks the haziness had diminished enough to allow me to diagnosticate pigmentary retinitis, and the patient then admitted that he had experienced the usual symptoms of this disease. Five years after the treatment there was no advance in the process of opacification.

CASE III.—Patient about sixty-five years of age. Lenses hazy, and a clear picture of the fundus could not be obtained. After about six-week's treatment it was possible to make a diagnosis of glaucoma simplex. The lenses have remained clear since treatment was given, more than three years ago.

We must thus conclude that the restoration of useful sight being the paramount desideratum, any complication which, independent of the lenticular opacity, diminishes visual power, contraindicates any form of treatment.

The popular conception of cataract held by the profession, and universally by the laity, is that it is a disease of old age, a deviation from mature vigor, and that it necessarily accompanies gray hair, tooth-

[1] Third paper. Read at a meeting of the Northwestern Medical and Surgical Society of New York, January 18, 1899.

lessness, and a tottering gait. This I unhesitatingly deny. It is well known that with advancing age the lens hardens and from a state of transparency may become almost amber-colored; but only in a very small percentage of cases does a degree of opacity ensue that is sufficient to produce enfeeblement of vision. It is likewise an undisputable fact that in many persons advanced in life, with positive evidences of general senility, we find the transparency of the lens absolutely unimpaired. In a small number of cases senility probably does play its part, and such patients should receive the same local and constitutional treatment that is given to subjects of other senile diseases. In the majority of cases of immature cataract, even in those in which advanced life may be an accompaniment, the absence of a single feature of senility, and the presence of rugged health and great physical and mental endurance plainly demonstrate the palpable error of regarding the occurrence of lenticular opacities as evidence of senile change; and holding to this opinion I have omitted the word senile and refer to my cases as uncomplicated immature cataract.

Two great factors enter into the production of incipient and immature cataract, namely, interference with the nourishment of the lens, and eye strain, acting independently or in combination. The lens is avascular and receives its nourishment by imbibition; hence, anything which interferes with the supply of blood to the choroid interferes proportionately with the acquisition of a supply of restorative material to the lens. In my paper above referred to I noted that in the great majority of my cases of cataract increased tension was observed, and this observation has been confirmed by the larger number of cases seen since that paper was written. Increased tension means increased intra-ocular pressure, which even in a slight degree must seriously interfere not only with the blood circulation, but with the liquid secretions as well. The veins being less resilient than the arteries would naturally be more easily compressed, and would be unable to empty the eye of its venous blood, thus damming back the arterial blood and decreasing the ingress of the arterial supply, that is, of the nourishment-bearing stream, which would thereby cause a serious interference with the nutrition of the ocular tissues. Consequent upon this retardation and diminution of the arterial supply the absorbent system suffers a marked functional inhibition, hence those structures dependent upon inhibition for papulum would from force of circstances be the first to suffer physical deterioration.

To the ill effects caused by a lessened supply of nourishing stream we must add another element in the abnormal constituents of the liquids which encompass the lens as shown in the following: In the paper above referred to I traced a connection between immature cataract and dyspepsia, which relation I desire to strongly emphasize. The term dyspepsia I employ in a generic sense, implying thereby not only imperfect digestion, but also the protean manifestations of incomplete digestion, decomposition, and degeneration of food, gastric or intestinal, or both. The ingestion of food is primarily for the purpose of renewing the tissues consumed in performing their functions. When, however, through defective metabolism this papulum is improperly prepared and noxious substances instead of nutrient material are elaborated, the whole general system suffers from a lack of restorative supply to replace the worn-out tissues, and it also suffers from a deposit in the tissues of excrementitious principles which if resorbed may cause auto-infection. Faulty metabolism is justly regarded—except by the minority which discovers micro-organisms as a causative factor in the production of every disease—as the chief determining cause of rheumatic and gouty arthritis, and since these products of disassimilation attack the avascular structures of the articulations it is certain that other structures similarly devoid of vascular supply, as is the crystalline lens, would likewise suffer an interference in constructive metamorphosis, and a corresponding interference in function. Imperfect metabolism must necessarily produce an abnormal nutritive fluid, and it is incontrovertible that if the lens be continuously immersed in a liquid which lacks elements necessary for the regeneration of its crippled cells, and contains agents likely to poison its healthy ones, its structure must undergo degenerative change, the first step of which undoubtedly is opacification.

That eye strain plays a most important rôle in the causation of cataract is generally admitted. The marked enervation so universally recognized as its accompaniment is direct evidence of its power to interfere with constructive metamorphosis, the consequence being that waste and repair become disproportioned and deterioration of structure occurs.

Subsequent to the publication of my articles above referred to, a new theory was deduced to account for the improvement in vision in cataractous eyes. The marvelous discovery was made that cataracts following a "natural" course remain stationary, more or less, and acuity of vision is increased. This was surprising; and as my observation of the progress of cataract had influenced me to adopt views diametrically opposed to this new theory, I subjected my records of cases of cataract seen prior to 1890 to a critical analysis, the result of which is here appended. The whole number of eyes seen was 35,

occurring in 21 patients. In 20 eyes the cataracts matured and the lenses were extracted. The shortest period between the first examination and the operation was about 18 months, and the longest period about 7 years. Fifteen eyes which did not mature thus remain, and 13 of these patients paid the last debt to Nature at periods varying from three months to five years following the examination. Ten of these showed decided advancement of the lenticular opacity, and a corresponding reduction in vision for distant as well as for near objects, and would undoubtedly have required operation later, had not intercurrent maladies carried them away. The remaining 3 passed away within less than a year after examination and conclusions are unjustifiable. There thus remain for final consideration two subjects, one of whom had been under observation for seven years before coming to me and remained under my observation for six years when an attack of pneumonia finished her earthly career. In the other case there was a general haziness of the lens, but good sight was retained up to the end, about seven years after I first saw the patient. The ophthalmoscopic picture in these two cases seemed from time to time to vary little if at all, but in neither case was there recession.

Analysis of these figures reveals that out of thirty-two eyes—the three patients that died so soon after examination must be eliminated—only two showed no signs of progression. With this personal experience as a guide, and personal experience is the only safe one, I dare not, to suit any fantastic whim, adopt as my motto, "*Ex duobus disce omnes.*"

In the further discussion of this peculiar and erroneous notion one is led to ask if due care were exercised in making the examinations of the patients who improved so "naturally." That nine were cases of cataract is beyond question, since they advanced to maturity, and ripened cataractous lenses were extracted. It is not unusual for patients to consult me having a "ready-made" diagnosis of cataract. This diagnosis is rarely made by a physician, but by some officious friend who instances identical cases in common friends. Eight such patients presented themselves during the past year; three had chronic conjunctivis, two had corneal ulcerations, one had corneal opacity, and two had acute iritis. According to its discoverers, the "natural" course of cataract, eventuates in an improvement of vision and an arrest of opacification of the lens. It then follows *a priori*, that cataracts will not ripen nor will operative interference be required. Just here a troublesome question obtrudes its ugly personality: If Nature prevents, even in a moderate degree, the maturity of cataracts, where do all the ripe cataracts come from? In three public hospitals of this city during the past year 494 cataracts were extracted, requiring 633 operations. This number is independent of that larger number operated upon in other institutions in this and in other surgical centers, as well as of those treated in private hospitals and at patients' homes, the whole number of which will assuredly reach into the thousands every year. Since it cannot be controverted that this is the outcome of the "natural" course of cataract, no one will deny that oculists must do something to interfere with Nature, and that something must be done right speedily.

My contribution to that something is the presentation of this my third paper on the absorption of immature cataract by conjoined manipulation and instillation. Reference will be made chiefly to the patients treated prior to January, 1894. Seventy-six patients (one hundred and thirty eyes) were treated between January, 1889, and January, 1894. Seven of these patients (thirteen eyes) passed away at dates varying from two to seven years subsequent to the treatment, all to the end having retained the benefit received. Two cataracts that matured were successfully removed by surgical aid. Advanced immature cataract in six eyes did not respond, the process being held in abeyance for a time; but later they ripened and extraction was performed. One case of advanced immature cataract in a patient with rheumatic arthritis was checked for a time, but afterward passed on to maturity and the lenses were extracted.

In making an estimate of the successful cases we must add to the number of patients living those who retained the benefit of the treatment up to the time of their death, and we thus have sixty-nine successful results with one hundred and eighteen eyes. To present the result of refraction examination of each one of these one hundred and eighteen eyes would require more space than should be devoted thereto, besides offering a mass of figures that would be simply bewildering; therefore, the following tabulation is submitted.

Thus in 12 eyes out of 130 the treatment availed nothing. Of these 12 there are 2 concerning which I have no information, but the remaining 10 were subsequently operated upon successfully. The cases treated from January, 1894, until January, 1898, one year ago, show a higher percentage of success, but statistics are not given, as the only question at issue is that relating to the permanency of the result obtained and this requires time for its demonstration. I am fully convinced by personal experience that the treatment of immature cataract by conjoined manipulation and instillation will pro-

duce a permanent and successful result, despite interested or farcical criticism to the contrary, but that it will modify every case I am not sanguine enough to expect until all humanity is cast from a single mold. It can be declared without fear of contradiction that while some are tall in stature and some short, some adipose in build and some spare, some fair in complexion and some dark, no single

specific for any one disease can possibly be found.

Several other methods of treatment, modifications of my plan, have been suggested and exploited since my papers were published, but I have still to find one that will do for my patients what conjoined manipulation and instillation have done. The instillation of a solution of eserin to reduce intra-ocular tension has been recommended in conjunction with a modification of my plan of manipulation. It is universally admitted by oculists that this remedy has in a number of instances lighted up grave attacks of acute iritis, exceedingly troublesome to manage, and in not a few cases followed by disaster to vision. The employment of such a dangerous remedy is, therefore, likely to prove more uncontrollable than the cataract it is proposed to relieve. The aromatic oils are being recommended as solvents for cataract. I thoroughly tested a number of them in my early investigations. The ones employed were oils of anise, caraway, chamomile, cinnamon, clove, coriander, cubeb, fennel, flagroot, horseradish, and mustard, but I failed to get even the slightest benefit from their use, and abandoned them.

It is necessary that some reference be made to the spontaneous absorption of mature cataract, reports of the occurrence of which appear from time to time in the papers, medical and lay. The term absorption in this connection is a misnomer, for it implies that the cataract is absorbed, the lens again becoming transparent. As a matter of fact, what happens is this: The opaque cortical matter softens, becomes liquid (Morgagnian cataract), and is absorbed; the nucleus either falls to the bottom of the capsule, or, as recorded by competent observers, in a few cases it is also absorbed. The histories of fifty cases have been collected by Nathanson and reported in *Zehender's Monatsblatt der Angenheilkunde*, 1898. I have under my care a case similar to one there referred to. The patient has been under observation for the past three years, has a myopia in each eye of about sixteen diopters, and two years ago, after exposure of the eyes to the glare of sunlight on a limestone road, a sudden dimness of sight was experienced in the right eye. On return to town, between two and three months later, examination of the eye revealed a large detachment of the retina below. Rest in the recumbent position, eserin, followed later by pilocarpin, instillations, hypodermatic injections of pilocarpin muriate to the production of marked diaphoresis for four weeks resulted in the reattachment of the retina. Six months later a cataract began to develop, and not knowing what effect manipulation might have on a reattached retina I decided not to employ my treatment for immature cataract, but to leave the case to Nature. About ten months later Nature made a complete report, showing a ripe cataract, but light projection was apparently lost over a space corresponding in size to about one-half the area of the previous detachment. Examination in October, 1898, left it questionable if any blind space existed, and the color of the opaque lens was less conspicuously white. In January, 1899, light projection in the four quadrants was good, and when the light from a concave mirror was passed in the line of a circle there was instantaneous recognition when the line was broken. There was also distinct ability to distinguish the presence or absence of large objects in places foreign to their usual position.

It is pertinent to the subject of this paper that a comparison be instituted between the result obtained in the so-called spontaneous absorption of mature cataract and that following absorption of immature cataract. In the first named there is a complete absorption of cortical matter and often the nucleus as well and when this occurs we have all the benefit of an extraction with none of its dangers; but the patient requires the usual high-power convex glass for general use, and a still more convex glass for reading. When, however, the nucleus is not absorbed, and descends in the capsule so that it partly occludes the pupil, it must be removed by extraction, but the operation is then more dangerous and often less satisfactory. In the absorption of immature cataract by my method the opaque fibers are changed to transparent ones, the entire lens (probably) remains; the large majority of these patients use the same

glasses after treatment that were used before opacification of the lens occurred, and they invariably declare that the eyes can be used without exertion, they being unaware of any effort.

In passing I would say that in making my examination of vision assiduous care is exercised to eliminate any and every element which might militate against repeated examinations being conducted on identical lines. The atmospheric condition is noted as being bright, sunshiny, dark, overcast, rainy, snowy, foggy, etc., and the same set of test cards has been used in all cases. These cards are kept in a closet with a glass front, the glass being kept covered with a heavy silk curtain. When not in use the glass door is closed and the cards are in darkness; this preserves the clearness of paper and letters and I am thus testing sight with the identical cards I have employed for the past nine years.

This subject may be thus summarized:

1. Immature cataract is due to local conditions dependent on general systemic causes.

2. Senility is rarely a direct, but may be a predisposing, cause.

3. Fluids containing perverted aliment resulting from defective metabolism supplied to the lens through its nutritive stream may be considered an exciting cause.

4. Deficient blood-supply, thus reducing the quantity furnished, may be considered a contributing cause.

The following conclusions may be drawn:

1. Immature cataract may be regarded as a largely preventable disease.

2. It may, by properly directed treatment, local and constitutional, be prevented, arrested, retarded or cured.

3. The circulation of the blood must be regulated.

4. The faulty digestion must be rectified.

5. Constant supervision of the eye must be maintained by a competent ophthalmologist, that eye strain be relieved, and all changes in refraction be promptly remedied.

6. Treatment by conjoined manipulation and instillation should be instituted at the earliest possible moment.

7. Finally, if local and constitutional treatment should not provoke a favorable issue they will establish a more nearly normal state of the ocular tissues, and if an operation be found necessary, this improved condition of the ocular structures will ensure a larger degree of success.

The accompanying plates (see frontispiece) are submitted as an exhibit of the ophthalmoscopic appearances present in these cases at the dates noted. In making the original drawings, from which the plates have been copied, rigid precautions were exercised to have the diagrams made under absolutely similar conditions in order that an accurate comparison might be instituted. Several of these diagrams were published in illustrations of cases reported in my second paper, and I cannot, nor do I think that any unbiased observer can agree with the criticism then made that these represent a single or unusual form of cataract. Both the striated and diffuse opacities are indicated, and as these are the varieties which generally are presented the pictures certainly do *not* represent an "anomalous form of cataract."

This selection of cases was made solely to present a pictoric representation of lenticular opacities before and after treatment, and the ones chosen were those in which there was the longest interval between the first and the latest examination, the object being to demonstrate that progress of the cataract was arrested and the absorption of the opacity was permanent.

THE PRESENT STATUS OF OUR KNOWLEDGE OF CHLOROSIS.[1]

By THOMAS S. SOUTHWORTH, M.D.,
of New York;
Attending Physician to the Nursery and Child's, Randall's Island, Scarlet Fever, and Diphtheria Hospitals.

In responding to the invitation of the President to prepare a paper on chlorosis, which would serve as an introduction to the discussion upon this subject, it has seemed to me to be more profitable to confine myself as far as possible to the consideration of those phases of the subject of which our knowledge has been modified or definitely confirmed by the ever increasing hematological investigations of the past decade. These investigations as I shall endeavor to show have in some instances disturbed our previously accepted divisions of anemia.

The so-called anemias are characterized either by a reduction in the number of red cells circulating in the blood, an oligocythemia, or by a reduction in the amount of the hemoglobin, designated as oligochromemia. Further, both red cells and hemoglobin may show reductions in varying degree, so that the hemoglobin value of the individual remaining corpuscles, the *valeur globulaire*, may be increased or diminished. These variations characterize certain divisions of anemia. Thus the percentage of hemoglobin in chlorosis is much lower than the percentage of red cells, while in pernicious anemia the percentage of hemoglobin is higher than the percentage of red corpuscles.

However, the plan was long ago adopted of dividing the anemias clinically according to the ab-

[1] Read at a stated meeting of the New York Academy of Medicine, May 4, 1899. For discussion see page 507.

sence or presence of a known and sufficient cause, in other words into primary and secondary anemias. In the present state of our knowledge we still adhere to this method, although the lines are at times drawn with great difficulty, and we must accept our somewhat arbitrary classification with a full understanding of its limitations, which are further enhanced by the possibility that we may at any time be called upon to divide or re-allot in accordance with our future acquisition of new light upon the subject.

Disturbances of the blood-forming function or organs enters to some degree into the causation of all anemias, as does also perhaps hemolysis or blood destruction, and the real point in classification is whether these dominate the clinical picture, while the disturbances of other organs play a dependant and minor part, in which case we call the anemia primary essential or idiopathic, or whether the preceding concurrent organic diseases, or deleterious influences are so prominent as to force upon our acceptance the belief that they stand in a direct causal relation to the anemia, in which case we must entitle it a secondary or symptomatic anemia.

The term "splenic anemia" although a convenient one to designate a class of cases in which the enlargement of the spleen is a notable symptom, has at present no real status, for it is a mixed class, some of the cases being symptomatic anemia and others being instances of Hodgkin's disease.

Until within a few years writers and teachers spoke of a simple anemia or a simple primary anemia and some still retain this division, but the hematologists have swept this away, for as Stengel distinctly states "there are no characteristics by which this may be satisfactorily recognized."

Those affections which are characterized by notable or distinctive alterations in the numbers and varieties of the white cells being at present grouped by themselves our classification of the anemias is therefore reduced to:

I. Primary; *a*, pernicious anemia; *b*, chlorosis.

II. Secondary or symptomatic anemia.

This latter large residual class of anemias becomes necessarily one of great interest, for, as we have just seen, it embraces all the cases of anemia which remain after the exclusion of pernicious anemia and chlorosis, and fortunately by its very name it forces upon us the obligation of discovering the cause of the anemia when we undertake the treatment. No sooner have we decided that an anemia belongs to the class of secondary or symptomatic anemia than the question confronts us: Secondary to or symptomatic of what? This brings us directly to a consideration of the possible causes of such anemias and this must necessarily be brief. They may be influences which act from without, in short, matters of environment, or they may be from within, conditions of actual disease. Hence hygiene, employment, dirt, hemorrhage, parasites, infectious diseases, organic disease and neoplasms, chronic diseases of nutrition, and toxic influences may stand in a causal relation. This list is not a long one and is often passed over lightly but a little serious consideration shows us that it really covers very nearly the entire field of internal medicine. The view that secondary symptomatic anemias show an approximately equal reduction in both red cells and hemoglobin is no longer tenable in the light of the results of extended series of observations. It has been shown that the reduction of hemoglobin is greater than the reduction of red cells. While this reduction is not very marked it is at times as great as that found in typical cases of chlorosis. Stengel's average in 100 cases of secondary anemia was red cells 88.6 per cent., hemoglobin 76.4 per cent., but in individual cases the reduction was often much greater. Rickets, carcinoma, tuberculosis, and syphilis show this most frequently and to such an anemia the term chloroanemia finds its most apt application.

Pallor, which may have a slight icteric hue, gastrointestinal disorders, anorexia, constipation, anemic murmurs, cardiac dilatation, palpitation, dyspnea, depression, weakness, languor, neuralgia, headaches, and in females menstrual disturbances may all occur in the secondary anemia as they do in the chlorotic woman. The differential diagnosis then, although easy in typical cases, is not always a simple matter. Examinations of the blood from which so much was expected do not solve the problem *at times* even when conducted by experts, as, in the absence of leucocytosis, characteristic differences are not uniformly present in these conditions. The clinical history of the patients and a painstaking investigation of their occupation, habits, and environment, together with the results of physical examination must be taken into consideration before we may make our diagnosis.

To return now to chlorosis with which this paper properly deals we find that its definition has been modified considerably in the direction of greater brevity. It is one of the primary anemias occurring almost exclusively in young women from puberty to the twenty-fourth year, characterized by a marked diminution in the amount of hemoglobin and attended by the usual clinical symptoms of anemia. The greenish-yellow color of the skin which is present in typical cases is by no means constant and many patients who in other respects correspond to the accepted clinical picture and show the customary alterations in the blood do not present this appearance.

Another fallacy which has been handed down to us is that blondes are more liable to become chlorotic than brunettes, but this opinion is no longer maintained. Moreover, as has been pointed out by Fagge, the chlorotic tint is best seen in those girls who are naturally of a dark complexion.

Since chlorosis occurs chiefly in women during the earlier years of menstrual activity, it was but natural that an effort should have been made to find out its cause in some derangement of the reproductive organs. Consequently the amenorrhea, which while probably symptomatic of the anemia, often appears before the other symptoms are developed to such a degree as to attract notice, was seized upon and paraded as a cause, but instances of menorrhagia also have been recorded by Trousseau and others. Further color was given to the above theory by Rokitansky in 1846 when he drew attention to the existence in certain cases which came to autopsy of a lack of development in the genital system. Niemeyer's statement is frequently quoted, that he had never met with a case in which the menses appeared early while the breasts were still undeveloped without the occurrence later of an obstinate chlorosis. Late establishment of the menstrual flow has also been linked with the disease. More commonly the symptoms do not declare themselves until two or three years after this epoch and Hayens found the average age of the onset of chlorosis in 52 cases to be seventeen and a half years.

Despite this close association of chlorosis with the menstrual life of the patients there seems to be on the whole no reason for assuming that there is between them an exclusive relation of cause and effect.

In 1856 Virchow stated authoritively that he had found in certain cases of chlorosis a congenital hypoplasia or retarded development in the circulatory system with narrowing of the lumen of the aorta and unusual thinning of its walls. Virchow's renown as a pathologist at once gave to this finding an established position as a potent etiological factor and no chapter on chlorosis has since that time been deemed complete without its mention. Fagge, however, than whom probably this century has produced no keener observer or more logical medical critic, points out that among Virchow's cases are several in which there was obstructive disease of the aortic or mitral valves, which in themselves may cause faulty development and narrowing of the aorta, and that such disease of the valves is not congenital but the result of endocarditis in early childhood. Moreover, not only have autopsies on many chlorotic patients shown normal aortas, but perhaps the strongest argument against the presence of such vascular hypoplasia, in any considerable proportion of cases, is found in the prompt and complete recovery of most chlorotics under suitable treatment.

Another epoch in the supposed etiology of this affection dates from the publication of the views of Sir Andrew Clark, which, by the way, did not originate with him, that the constipation, which is so commonly associated, results in the absorption of toxic products. In this connection, the term copremia is most commonly employed. Certainly, constipation is a common symptom, and it is a matter of general observation that the relief of this condition favors the action of other measures for the cure of the disease, but any theory that hemolysis, pure and simple, produces the chlorotic condition of the blood seems to have been definitely disposed of by Van Noorden and others, who have shown that urobilin, which is invariably increased in the urine when there is excessive destruction of red cells in the organism, is present in the urine of chlorotics in decreased or at best only in normal quantities. This is an important fact.

Forchheimer takes the view that hemoglobin is chiefly manufactured in the intestine, and that intestinal putrefaction interferes with its production. Of this he considers the reduction of urobilin in the urine an important sign.

The nervous system and especially the sympathetic system offers us an extremely interesting field for speculation, the more so because certain recognized predisposing causes, such as fright, shock, grief, disappointed affection, homesickness, etc., may act through this little understood channel upon the innervation of the blood-forming organs and influence their output.

The blood-forming organs themselves when interrogated by the pathologist throw no light upon the subject, as they present no characteristic changes. The spleen is frequently enlarged. Anemia, small hemorrhages and fatty degeneration of the important abdominal organs may be present as in other forms of advanced anemia.

Much interest has attached of late years to certain changes in the gastro-intestinal tract. Dilatation of the stomach, gastroptosis, fatty degeneration of the gastric tubules and gastric ulcer, have all been found with considerable frequency, but these are all open to explanation of being secondary phenomena, while if they be primary lesions the question is debatable whether the resultant blood condition should not be classed as a secondary anemia.

The suggestion that chlorosis is an infectious disease rests chiefly upon the occurrence in certain cases of venous thrombosis and the occasional presence of fever and of enlargement of the spleen. Micro-organisms have been found in the blood of patients

with these symptoms, but the proposition will not hold good of all chlorotics.

Thus far no mention has been made of change of climate and environment as seen in the immigrant class, nor of the influence of overwork through long hours in close, badly ventilated, and often poorly lighted workshops or apartments, with the hurried consumption of coarsely prepared and unsuitable food. These are of undoubted importance in the cases which occur in the ranks of the employed. But because the patient comes from the well-to-do classes it by no means excludes the possibility of an improperly adapted diet hygiene with overstudy, late hours, dancing, and excessive fatigue. Therefore, when all has been said on the subject of etiology we find no single constant cause operative in all cases but various factors which serve to disturb the balance of the hemogenetic organs, which although they have previously managed to keep up with the demands made upon them now give way under a strain which is put upon them at puberty when the body is undergoing a rapid development, which can only be accomplished properly under favorable conditions.

The symptomatology of chlorosis has much in common with the other anemias, yet the careful statistical investigation of individual symptoms has developed much that is of interest. When some emotion or other etiological factor acts through the nervous system the onset may be sudden. The same is true when there has been some decided alteration in the patient's habits of living or her environment, as in change of rêsidence to a foreign country, but otherwise the onset is usually gradual and may not excite remark among the friends until some single prominent symptom, like amenorrhea, fainting, dyspnea, or palpitation forces itself on the notice of the patient or her family. With the younger patients, as in the anemias of childhood, the first indication may be a disinclination to engage in their usual sports, exercise, or more active duties. Headache is more common in the early stage. The pallor which, as we have seen, does not always exhibit the characteristic tint so commonly described is more certainly determined by an examination of the mucous membranes of the mouth and conjunctiva since certain cases present a vasomotor dilatation of the face which may be misleading. These latter cases have been designated chlorosis rubia or florida. It may happen that the embarrassment incident to the medical interview may temporarily put a fair degree of color into the face of the patient.

Contrary to the usual findings in cases of secondary anemia the subcutaneous fat is often rather increased than diminished, although this is not true of all cases. Explanations of this phenomena are varied, such as that the persistence of the fat is due to feeble oxidation owing to the reduced amount of oxygen-carrying hemoglobin in the circulation, or that it results from the avoidance of exercise while consuming the usual quantity of food, or again because the patient from a feeling of chilliness dresses warmly and thus lessens heat radiation and production with reduced combustion of the body fats.

Edema when it occurs is present about the eyes and ankles but seldom to any marked extent. Pigmentation of the skin about the joints is at times found as in other diseases associated with anemia. Few cases exist without more or less disturbance of digestion. When constipation is a factor the breath is offensive. The appetite is often lacking or perverted and it is customary to state that pickles or sharply spiced foods are more willingly eaten and that there is often a craving for chalk and slate pencils.

Hayem, who first maintained that the dyspepsia of chlorosis is due to a deficiency of hydrochloric acid, later found, in a series of 70 cases, one-half in which there is hyperpepsia and some cases in which there was an excess of hydrochloric acid; while Oswald found hyperacidity in 95 per cent. of his cases and concluded that neither deficiency of hydrochloric acid nor motor deficiency in the stomach played any part in the dyspeptic disorders of chlorosis. He consequently decried as injurious the indiscriminate giving of hydrochloric acid in this disease. More attention should doubtless be given to the position of the stomach and the physical condition of its walls for while Hayem records the existence of dilatation in 27 out of 37 cases examined more recent writers have considered that some degree of gastroptosis is present in a large proportion of the cases, and that the severer the case the more probable it is that one or both of these conditions exists.

Nausea and vomiting which may take the form of morning regurgitation of food is not uncommon. Epigastric distress and pains which are neither constant in degree nor in location are of frequent occurrence. Constipation with the accumulation of hard scybalous masses has already been sufficiently referred to. In the presence of a considerable anemia, which affects as well the nerves and the nerve-centers, it is not surprising that there should be headache depression, occasionally amounting to melancholia, hysteria hyperesthesia, and neuralgia, whose dependence on the anemia is best indicated by their yielding more surely upon the administration of iron than with the use of any other measures. While the course of chlorosis is usually apyretic and the temper-

ature may be even subnormal, some cases undoubtedly show some continuous or irregular elevation. This has been ascribed to fatigue (Hayem), to constipation, and the absorption of toxic products from the bowel (Potain and E. Guam), or to the existence of complications. While some analogy is found in the fever which accompanies pernicious anemia, its presence should always excite suspicion and before it is accepted as symptomatic of the chlorosis other complications and especially tuberculosis should be carefully sought for and excluded.

Of the various disturbances of the circulatory system, palpitation is most commonly complained of by the patients, and this it may be which leads them to seek medical advice. If the anemia is marked even moderate exertion, or any sudden emotion serves to bring it into prominence. Vascular murmurs are of frequent occurrence, and some of the best examples are to be found in this disease. Richardson found the so called venous tumor, or bruit de diable in the vessels of the neck, in fifty per cent. of 180 cases, but Henry thinks this is probably a low figure. This murmur was much more frequent on the right side alone, 33.3 per cent., than on the left, 6.1 per cent., while on both sides it was audible in 11.1 per cent. The cardiac area may be normal, but dilatation may occur with some increase in cardiac dulness. As the anemia increases murmurs develop over the precordium. These are usually first over the pulmonary area, and then may be heard over the mitral, tricuspid or aortic areas. Barr found bruits in 115 out of 205 cases. Of these 56 were heard at the base, 13 at the apex, 24 at both base and apex, and 22 at base, apex, and back. The wider the audibility of the murmur the more liable was the heart to be dilated, and the more readily was it affected by treatment. Eichorst, who seems to have observed a group of more severe cases, as shown by the more general dissemination of the murmurs, reports in 38 chlorotics a murmur in the pulmonary area in 30, tricuspid in 28, mitral in 27, aortic in 13 cases. The murmur was loudest in the pulmonary area in 21 of the patients, mitral, 9, and tricuspid, 8. The various explanations offered for these murmurs would involve a consideration of the whole mooted subject of hemic and functional murmurs, including relative insufficiency of the valves. The pulse is susceptible to considerable variations even in the same individual, but there seems to be a general agreement that it is readily accelerated to a moderate extent, and that, as a rule, the blood pressure is lowered. Dyspnea is a troublesome symptom, and increases with the reduction of hemoglobin.

Dowd in his series of 31 cases examined in Roosevelt Hospital was impressed with the fact that the severity of the symptoms was dependent rather upon the lowered hemoglobin than the paucity of the red corpuscles.

The most notable characteristic of chlorotic blood, as has been stated above, is the extreme reduction of the hemoglobin while the red cells suffer to a relatively much slighter degree. In placing a drop of fresh blood upon the slide for microscopical examination we notice that it is thin and pale, and that it coagulates more rapidly than normal although we are told that the fibrin is not increased. The individual red cells are noticeably colorless, especially in their centers, and there is a uniform decrease in size. Only when the case is a severe one do very small and very large cells (microcytes and megalocytes) appear. The blood-plaques are largely increased in number, and Hayem, who considers them the early form of the colored corpuscles, thinks that in this disease their development into complete red cells is retarded. Certain writers have maintained that there is a condition of hydremia and that the actual volume of the blood is increased.

The very valuable series of examinations made and tabulated by Thayer of 63 cases, and by Cabot of 77 cases, give us an excellent opportunity of studying the relation of the red cells and the hemoglobin. Their averages for their series correspond strikingly. They are respectively: Red cells 4,096,544 and 4,500,000 per c.mm. Hemoglobin 42.3 per cent. and 41.2 per cent., or about half the normal amount of hemoglobin for each cell present. These averages would at first sight seem to indicate that the number of red cells is not greatly reduced, and indeed that is true of a considerable number of the cases, but in the proportionately smaller number of severe cases the count of the red cells may be greatly reduced. Cases are recorded in which the counts were as low as 1,953,000 (Thayer), 1,932,000 (Cabot), 1,500,000 (Stengel), with hemoglobin respectively, 17 per cent., 19 per cent., and 20 per cent. Yet hemoglobin of only 20–35 per cent. may be found with the red cells from 3,000,000 to 4,000,000 per c.mm.

It is with the development of the more marked oligocythemia that we begin to find other changes common to all severe anemias, namely, variations in size, poikilocytosis, degenerative changes and the appearance of nucleated red corpuscles. These changes are seldom as marked as in the severe secondary anemias of the same grade. The nucleated red cells are almost invariably normoblasts and the megaloblasts so common in pernicious anemia are seldom found. Reinert's 247 tabulated cases in which the red cells were 4,000,000 and over in but 99 cases, and fell below 4,000,000 in 148 cases,

are very interesting as showing that the cases of chlorosis abroad advance to a more extreme degree than with us, probably because the patients do not seek treatment as early.

It may be definitely stated that there is no leucocytosis in uncomplicated cases. Cabot's series averaged 7485 white cells per c.mm. and Thayer's 8467 per c.mm. Although there is no increase in the total number of the white corpuscles there is at times a relative increase in certain forms, that is of the mononuclear forms, a so-called lymphocytosis. This led Neusser to advance the view that chlorosis could be divided into lymphatic and splenomyelogenous types. The former was associated, he thought, with enlarged glands and the so called lymphatism, the latter with enlargement of the spleen and pain in the bones. Neusser's views, however, no not seem to have been substantiated by others. The finding of an occasional stray myelocyte has no significance.

The specific gravity of the blood which sinks in direct proportion to the loss of hemoglobin is consequently much lowered. Cabot states that 1030 is not uncommon and Stengel quotes 1020 in one case. Biernaki should be recorded as standing alone in his opposition to the generally accepted view that the iron in the blood is reduced in quantity. In the fluid portion of the blood the water is increased and the amount of albumen is decreased. Opinion is divided with respect to an increased alkalinity of the plasma. In the regeneration of the blood under the use of iron the red cells first show increase in numbers, and later improve in size, weight, and color.

The chief difficulty in the diagnosis of chlorosis, by examination of the blood, lies, as has been said, in differentiating it from secondary anemia, from which at times it may be indistinguishable if the latter presents no leucocytosis.

The chief differences between the two as stated by Cabot are as follows: in secondary anemia the red cells may be reduced lower in numbers for a case of equal severity. Their size and shape is more varied while not exceeding nor usually equaling the normal size. Necrobiotic or degenerative changes with polychromatophilia occur earlier and are more marked. Nucleated red cells are more common, chiefly normoblasts. The hemoglobin is relatively low but does not show the same disproportion which characterizes chlorosis. There is often leucocytosis with the polynuclear cells increased in number and the lymphocytes diminished. These are the general rules, yet in young women a careful study of the clinical features of the case and of the physical signs must often be depended upon to determine the question.

An interesting pallor is to-day less fashionable and less prevalent than it was some decades ago. The impetus which has been given of late years to outdoor sports is leading to a healthier life. The available hematonics have been considerably increased in number. The patent pill for pallid persons lies exposed on every drug-store counter and fills the daily newspaper with its flaring advertisement. Moreover, the public itself is better informed in such matters, and the terms thin blood, poor blood, and even anemia, with its every variety of popular pronunciation, are more or less correctly applied by the laity. Consequently assistance of some kind is sought for earlier and this assistance is more efficient than formerly. We may at least assert confidently that extreme cases of chlorosis are now met with less frequently among the more intelligent classes.

Although the dictum of Immerman is a true one, as quoted by Henry, that "scarcely any point in therapeutics is so fully established as the remarkable efficiency of iron in removing all the symptoms of chlorosis," it is equally true that while the haphazard use of a few time-honored preparations will produce favorable results in a considerable number of cases, many failures will inevitably follow such a plan. The treatment of chlorosis and anemia is not simply *iron*, but it is the administration of a suitable preparation of iron, together with a proper regulation of the patient's mode of life and the intelligent choice of measures for the relief of disturbed functions. It is, therefore, not unusual to meet with patients who have been under routine treatment for considerable periods without notable improvement, who make rapid strides as soon as they come into other hands and are put on treatment which is judiciously outlined in accordance with the individual needs and indications. When fatigue has been a contributory agent, rest in bed may be imperative, for this reason some patients who do not improve while continuing their usual occupations improve steadily after they enter a hospital. Removal to a different environment, stimulation of the skin by bathing, and the establishment of a better circulation by friction and massage may be of great assistance. Some degree of dyspepsia exists in the majority of chlorotics and often this must be relieved before iron will be efficacious or perhaps even be tolerated. This has been maintained by Hayem, and on this basis Pick treated sixteen patients by lavage with great success. He was convinced that it produced better results in the improvement of digestion than were obtained by drugs. P. Le Gendre favors the use of simple bitters or strychnin or trucia before meals; the administration of hydrochloric acid, if there be proven to be deficiency of secretion, or full doses of alkalies if

hyperacidity exists; while abnormal fermentation is to be checked by bismuth salicylate, naphthol or chloroform water 3 to 4 hours after meals in cases of dilatation.

The diet of the chlorotic should be simple and adapted to the digestive powers of the individual. Milk may usually be given freely. Van Noorden would limit the fats and carbohydrates for plump patients, and give them more freely to lean ones. Meat rare or raw may be given to both, and in itself contains iron, and with egg furnishes albumens, which are said to be deficient. A considerable controversy which is not yet ended was initiated by Bunge when he advanced the theory that the inorganic preparations of iron subserve their purpose indirectly by combining in the intestines with the sulphides which are there formed as the result of abnormal decomposition, and thus allowing the normal absorption of the organic iron compounds present as nucleo-albumens in the food to proceed without interference. Even the most active opponents of this theory are forced to admit the efficacy of inorganic iron compounds, and the question whether inorganic iron is directly absorbed into the blood, or acts as a stimulant to the hematopoietic organs, or is only of value in the way that Bunge has suggested, is still an open question. Authorities seem to differ as to the amount of iron which it is necessary to administer, and the advocates of smaller doses base their claims on the very small amount of iron contained even in the normal, healthy human body, and remind us that nearly all the iron given by the mouth is recoverable in the stools. It is possible that when the digestive tract has been well prepared for absorption, the small doses are proportionately more fully taken up. However, it is common experience that large doses are often efficacious when small ones have failed. Of this phenomenon Bunge's theory furnishes us our only explanation. While the weight of opinion seems to be in favor of the use of inorganic preparations of iron in massive doses, the usefulness of organic preparations in certain cases cannot be denied. The favorite forms of giving iron are as Blaud's mass, sulphate of iron in Startin's mixture (Clark's), lactate of iron (Quincke), Liq. ferri sesquichlorid G.P. (Israel), tinct. ferri chlorid (Nothnagel), proto oxylate of iron (Hayem), to which may be added the long list of officinal combinations of iron with the vegetable acids, and the non-officinal albuminates, peptonates, and preparations of hemoglobin and the nucleo-albumens. In general, it is safe to say that the best guide to the choice of a preparation of iron is the condition of the stomach. Townsend, in several groups of cases treated by different methods, secured the most rapid increase of hemoglobin when beta naphthol, grains 2 were given with 5 of Blaud's mass, thrice daily, thus securing intestinal antisepsis. Forchheimer selected solol and hydronaphthol as the most efficient antiseptics, giving them in 5-grain doses with iron. The hypodermatic administration of iron which has been used considerably upon the Continent has met with little favor here on account of the pain and irritation caused by most preparations. Da Costa, however, claims to have eliminated this by the use of 15-minim doses of a twenty-per-cent. solution of the unofficinal ferri et mangani citras.

Relief of the associated constipation of chlorosis, and of that which is induced by many of the iron preparations is imperative for the attainment of prompt results. Cascara has of late been much used for this purpose and is often better tolerated by the stomach than the salines and natural purgative waters which have long held their position. Sir Andrew Clark combined the laxatives with the irons in Startin's mixture above mentioned. He also employed pills of aloes, myrrh, and iron. Arsenic has little effect alone but is often very valuable in combination with iron. The addition of strychnin is frequently of service for its general tonic effect upon the stomach and upon the circulatory and nervous systems. The subjective sense of improvement is not infrequently more prompt under its use. In a similar manner digitalis by slowing and steadying the cardiac action will add to the patient's feeling of well being. Manganese seems to have failed to fulfil the claims which were made for it. Oxygen, although useful, has no advantages commensurate with its cost. There is a general consensus of opinion that treatment should not be abandoned when the subjective symptoms are relieved, but to avoid relapse should be persisted in until the hemoglobin reaches or approximates the normal.

THE HISTOLOGY OF DUPUYTREN'S CONTRACTION OF THE PALMAR FASCIA: REPORT OF MICROSCOPIC EXAMINATION IN TWO ADDITIONAL CASES.

By J. B. NICHOLS, M.D.,
of Washington, D. C.;
Demonstrator of Histology in the Medical Department of Columbian University.

In "A Clinical Study of Dupuytren's Contraction of the Palmar and Digital Fascia," published in the *American Journal of the Medical Sciences* for March, 1899, page 285, I reported a microscopic examination of the lesion in one case and cited the microscopic studies of the disease found recorded by Richer, Chevrot, Anderson, and Langhans. Since that article was written opportunity has been pre-

sented for making microscopic examinations in two more cases of Dupuytren's contraction, which are here reported.

Case I.—W. H. D., born in New York in 1826, was a sailor and engaged in heavy labor from 1865 to 1889, and after that time was a watchman or lived, without working, as a pensioner. He was subject to occasional attacks of asthma and after 1894 had rheumatism in the left leg. In 1882 the little finger of the right hand began to contract and the flexion continuously increased through the remainder of his life, in 1897 it being stated to be worse than it had been a year previous. The left little finger also contracted progressively from 1892.

When examined, April 29, 1897, the following conditions were found: In the right hand a prominent elevated band extended across the palm from near the wrist to the little finger, with marked indrawing of the skin opposite the metacarpophalangeal joint; the band continued along the radial side of the little finger to the base of the distal phalanx, causing well-marked contraction of the finger, the proximal phalanx being flexed on the metacarpus to an angle of about 120 degrees, and the distal phalanx flexed to about 135 degrees. Forcible extension of the finger caused marked pain along the contracted band. There was also induration and puckering of the skin opposite the metacarpophalangeal joint of the right middle finger, but no contraction of the finger. In the left hand there were slight contracted bands with induration and indrawing of the skin along the lines leading to the little finger and thumb, which were slightly contracted.

The patient died of pulmonary edema December 25, 1898, and microscopical examination was made of the tissues in the palm including the contracted band running to the little finger of the right hand. The band causing the contraction was plainly visible to the naked eye as a well-marked dense, fibrous band belonging to the palmar fascia, situated in the subcutaneous tissue at a greater or less distance from the corium. In cross section the band was of oval shape, measuring about five millimeters in the long axis and three in the short axis; the long axis lay parallel or slightly oblique to the surface of the skin. The cut section of the band was of a dense, glistening gristly appearance and feeling.

Microscopic Examination.—Toward the wrist the band was separated from the corium by an interval occupied by areolar or loose connective tissue, and some adipose tissue, coils of sweat glands, and blood-vessels. Opposite the metacarpophalangeal joint, where the skin was depressed, the contracted band lay closely adjacent to the lower surface of the corium with nothing intervening—not even sweat-glands, which were suppressed or pushed aside in this situation. Although the cord adjoined the corium the tissues of the two were distinct and did not merge into each other. The band consisted of a dense longitudinal aggregation of firm fasciculi of white fibrous tissue, similar in general to the tissues of normal palmar fascia; it was substantially a hypertrophy or increased development of a circumscribed longitudinal tract of the palmar fascia.

At a point examined toward the wrist the band exhibited a markedly low relative proportion of connective tissue cells among the fibrous elements. In some of the fasciculi the cells were very scarce and scattered, the fibers being compacted together in exceedingly dense and solid non-cellular masses. In this situation, also, the band was notably non-vascular, the slender blood-vessels present among the fasciculi of normal palmar fascia being here almost entirely absent. At another point examined (at the depression of skin over the metacarpophalangeal joint) the connective-tissue calls were very abundant, fully as numerous as in normal fascia. The blood vessels in this portion of the band also were quite scanty, though somewhat more abundant than in the other situation examined. They were capillaries or very small vessels with only a scanty adventitia, and were not surrounded and accompanied by any abundance or proliferation of connective-tissue cells.

The stratum corneum of the skin was somewhat thickened, apparently from non-use of the hand and lack of attrition of the surface; the remaining portions of the skin, in the sections examined, were not materially if at all thickened. Inversions of the skin, so that a tip of epidermis and corium (drawn by the traction of shortened fibrous bands) projected entirely underneath the surface skin, were present and conspicuous. The sweat-glands were unaltered, except in being absent at points where the band was closely apposed to the corium. Otherwise no abnormality was observed in the tissues surrounding the affected fascia. A few Pacinian bodies were seen alongside the band.

Case II.—J. D. P., born in Tennessee in 1819, was a farmer until 1855, a soldier from 1855 to 1882, and after the latter date an inmate of a Soldier's Home. From 1871 he was subject to occasional attacks of chronic rheumatism. About 1891 or 1892, while occupied in raking leaves, a contraction of the fascia gradually developed in the right palm, unattended by pain.

When examined March 10, 1896, in the right palm there was a slightly elevated band of contracted fascia running from the palm to the middle phalanx of the little finger, flexing this phalanx to an angle of about 135 degrees. There was also a slight band to the ring finger; the left palm was scarcely affected. The patient was markedly senile. No further change was noted in the condition of the Dupuytren's contraction. The subject died May 18, 1899, from circulatory disturbances resulting from hypertrophy of the heart, and the skin and underlying tissues including the contracted fascia leading to the right little finger were subjected to microscopical examination.

To the naked eye the band causing the contraction appeared as a dense fibrous band, with a glistening grisly appearance and feel, situated in the subcutaneous tissues immediately beneath the corium.

Microscopic Examination.—Cross sections of the affected tissues were made at two points, at the transverse line in the palm opposite the metacarpopha-

langeal joint, and at the line of junction of the little finger with the palm. At both these points the band appeared as a dense longitudinal rounded or oval aggregation of white fibrous tissue, not exhibiting any marked division into fasciculi; its tissue was not essentially different from that of normal fascia, being a hypertrophic development of the latter. The band was situated in the layer of subcutaneous fascia, and was in immediate juxtaposition with the lower surface of the corium; the band and corium, though in contact, were distinct structures and not continuous with each other. Among the closely aggregated fibrous elements of the band nuclei of connective-tissue cells were abundant and prominent, elongated in form (rounded or polygonal in cross section). The band contained few vascular channels, a few scattered capillaries being present without any accumulation of connective tissue cells surrounding them.

At the base of the little finger the band was elliptical in cross section, about three by two millimeters in size, the longer axis being transverse. In this situation two Pacinian bodies were observed alongside the band. Over the metacarpophalangeal joint the band for a short distance was composed of two divisions side by side, giving a combined transversely oval cross section 3 15 by 2.5 millimeters in size. One of the divisions of the band at this point was connected with a large fascial band extending downward. Aside from some thickening of the stratum corneum (probably due to non-use of the hand) the skin was not materially thickened or altered, and no other abnormalities were observed in the tissues surrounding the hypertrophied band.

A comparison of the histological conditions in these cases with those found in the case of H. D. J. (published in the journal above cited) exhibits some noteworthy points. In the case of H. D. J., the contraction was of recent development, about eighteen-months' standing; the contracted band contained a great abundance of connective-tissue cells, and numerous small blood vessels surrounded and accompanied by a great profusion of cells passed among the fibrous fasciculi. In the cases here reported the contractions were of long standing, having existed sixteen and eight years respectively, though in Case I., stated to have been continuously progressive. As compared with the case of H. D. J., the contracted bands were less vascular; the vessels present were unaccompanied by any abundance of cells in their adventitia, the connective tissue cells among the fibrous elements were less numerous and at one situation in one of the cases very much diminished.

These observations go toward indicating that in the early or developing period of Dupuytren's contraction the cellular and vascular elements occur in great abundance; while at a later stage, when the lesion is fully developed and stationary the cells and vessels diminish, leaving the abnormal tissue a dense fibrous mass; and that the hypertrophied fibrous bands are developed by the activities of the abundant connective-tissue cells, which are proliferated in especial profusion along the course of the small blood-vessels. The lesion is essentially a hypertrophy, the new tissue being similar to the pre-existing normal fascia. Any etiological explanation of Dupuytren's contraction would have to take into account the active proliferation and the fibroplastic action of the connective tissue cells and their relation to the vascular elements. The presence of Pacinian bodies in all the three cases microscopically examined by me is perhaps worthy of mention.

CLINICAL MEMORANDUM.

TREATMENT OF SUPPURATION OF THE MIDDLE EAR WITH ACETANILID.[1]

By GEORGE F. LIBBY, M.D.,
OF PORTLAND, ME.;
ASSISTANT-SURGEON TO THE MAINE EYE AND EAR INFIRMARY.

THE following cases have been selected as fairly representing the results of the use of acetanilid in the treatment of suppuration of the middle ear in a series of seventy-five patients treated during the past three years. Fewer acute cases (3) are mentioned because of the greater tendency of the patients toward recovery.

CASE I.—A. F. F., female, aged fifteen years, a student. Discharge from right ear of three-weeks' duration, occurring one week after attack of grip. The hearing was entirely lost in this ear. The discharge was profuse, the pulsating vessels of the tympanum forcing it into the auditory canal at each heart-beat. The edge of the perforation in the membrana tympani was covered by granulations. These were removed with Hartmann's forceps, and their bases destroyed by applications of nitric acid. Each day for twelve days the ear was cleansed with hydrogen peroxid and carefully dried with absorbent cotton twisted on a probe, after which a small amount of finely powdered acetanilid was insufflated. On the thirteenth day the discharge ceased; on the following day the perforation was closed and hearing improved 10 per cent.; and after inflation of the middle ear twice a week for two more weeks the hearing was restored to normal.

CASE II.—A. S. G., female, aged fifty years. Discharge from left ear for two days. Cleansed with hydrogen peroxid on cotton, dried, and insufflation of acetanilid daily for five days. The discharge stopped on the sixth day and the membrane was healed on the ninth. Hearing of the affected ear improved 15 per cent.

CASE III.—A. V. B., aged eleven months. Slight purulent discharge from left ear for six weeks. Cleansed the ear and insufflated acetanilid daily for three days. The discharge ceased on the fourth day, and the perforation closed immediately. Hearing not recorded on account of patient being an infant.

Of the chronic type I report seven cases.

CASE I.—C. L., female, aged three years. Discharge from both ears for two years. Patient tuberculous and suffering from acute meningitis when seen by me in consultation with family physician. Cleansed the ears with

[1] Read before the American Laryngological, Rhinological and Otological Society, at Cincinnati, Ohio, June 3, 1899, and before the Maine Medical Association at Bangor, Maine, June 7, 1899.

dry absorbent cotton and applied acetanilid daily for five days. The discharge, which was very free, stopped on the sixth day; recurred on the seventh in the right ear only; ceased on the ninth day and had not returned in either ear at the last report, three months later. Hearing improved, per cent. not noted.

Case II.—E. M. W., male, aged twenty-one years. Occupation, clerk. Suppurative discharge from left ear of 18-years' standing. The membrane was absent save a very narrow margin above, and the tympanum was covered with granulations. The discharge was very foul. Cleansed the ear daily with hydrogen peroxid and made occasional applications of a one- or two-per-cent. solution of nitrate of silver and finally of lunar caustic until the granulations were destroyed. These applications were always followed by a complete filling of the tympanum with acetanilid. This treatment was continued every day for three months. The discharge decreased and became less foul-smelling but did not entirely cease. I have just learned, two years from the date of beginning treatment, that my patient is dying from phthisis. No improvement in hearing noted.

Case III.—F. B. M., female, aged thirty-two years. Occupation, housewife. History of discharge from right ear at intervals of a few years for past sixteen years. When first seen by me one year ago the right meatus was two-thirds full of foul, pasty pus and the lower half of the membrane was absent. The pus was removed with an ear-scoop, and the canal and tympanum cleansed with hydrogen peroxid. Acetanilid was freely insufflated after the cleansing and drying, twice in four days. The discharge stopped on the fifth day, recurred on the fifteenth, when the above treatment was repeated; ceased on the following day, and had not reappeared one month later, at last report. Hearing improved 25 per cent.

Case IV.—H. C. S., male, aged thirty years. Occupation, druggist. Diabetic history. Frequent discharge from right ear for twenty-five years. Patient consulted me one year ago, when I observed a collection of foul pus below a small perforation in the superior posterior quadrant of the membrana tympani. Cleansed with hydrogen peroxid and insufflated acetanilid every other day for ten days, when the discharge ceased and the membrane healed. No recurrence at this writing. Hearing not improved.

Case V.—S. L. E., female, aged seventeen years. Family and personal history of scrofula. Patient had been confined to the house on account of injuries received from a fall, and her health was much impaired. There had been a fetid discharge from both ears at intervals of a few months for four years. At my first visit, seven months ago, this discharge had returned with increased profuseness. Daily cleansing of the ears with cotton swabs saturated with hydrogen peroxid and the free insufflation of acetanilid was instituted and carried out for two weeks, with marked diminution of the discharge. There was 35 per cent. improvement of hearing in the right ear, and 50 per cent. in the left. Soon afterward I lost sight of the patient, but not before providing her with an outfit with which to personally carry out the treatment.

Case VI.—A. H. S., male, aged eight years. History of suppuration of both ears for six years. When I first saw the patient, six months ago, his mother stated that he had complained of pain in the left ear for ten days and in the right for twenty-four hours. Inspection showed perforation of each drum membrane at the lower end of the manubrium. There was a little serous discharge from the right ear, and more, of a seropurulent nature, from the left; and pulsating of the vessels of the tympanum. I cleansed the ears with dry cotton and applied glycerite of carbolic acid daily for five days. This relieved the pain but the discharge became purulent in both ears. I then began the daily use of hydrogen peroxid and acetanilid. The discharge ceased in the right ear in three and one-half weeks, and in the left in five weeks. Both membranes healed. There was a recurrence in the right ear two months later, but this soon yielded to the same treatment. Hearing improved three per cent. in the right ear.

Case VII.—E. E. W., female, aged nineteen years. Health good. History of a discharge from both ears nine years ago, and recurrence in the left during the previous two weeks. Inspection showed two perforations; the smaller was in the posterior superior quadrant of the membrana tympani, and its edge was covered with one granulation the size of the end of an ivory crochet-needle; the larger was in the lower half of the membrane near the border. I removed the granulation and applied nitric acid to its attachment. I then cleansed the ear and applied acetanilid in the usual manner twice a week for three weeks, when the discharge ceased. No improvement in hearing was noted. The discharge has reappeared within the past three weeks, six months after the last visit, and the ear is now progressing favorably under the same plan of treatment.

Case VIII.—K. C., female, aged twenty-three years. Health fair. Consulted me five months ago. History of discharge from left ear one year, six months, and one month previous. Inspection showed total loss of the membrane and ossicles. After cleansing with hydrogen peroxid I applied a two-per-cent. solution of silver nitrate and insufflated acetanilid daily for two successive days. The discharge ceased on the third day and had not returned one month later, at last report. No improvement in hearing.

Case IX.—A. F. F., female, aged fifteen years. Occupation, student. Patient somewhat anemic and not strong. Left ear had discharged at intervals since an attack of scarlet fever at three years of age, and hearing had been almost lost in that ear. At time of consulting me the discharge was abundant and fetid, with a large perforation in the anterior superior quadrant of the membrane. I cleansed the ear with peroxid of hydrogen, applied glycerite of iodin to the inflamed tympanic membrane and adjacent auditory canal, and then filled the inner fourth of the meatus with acetanilid closely packed. The following day there was a very little moisture at the outer edge of the impacted acetanilid. The second day the ear was dry, and there had been no recurrence of the discharge at the date of the last report

three months later. The acetanilid was gradually wiped out or fell out, and exposed to view through the old perforation a healthy condition of the tympanum of a formerly chronically suppurating middle ear. The hearing improved gradually until it became half of normal.

Case X.—C. H. T., male, aged seventeen years. Occupation, student. Health fine. History of purulent discharge from the left ear six months before which yielded to treatment but recurred two weeks before I saw him and had continued four days. Cleansed for two successive days with hydrogen peroxid, carefully dried and insufflated acetanilid. The discharge ceased on the third day. This case was complicated with a very painful furuncle of the external auditory canal. This was opened and the same treatment applied with happy results. There was no noticeable change in hearing, as was to have been expected in so short a time.

As peroxid of hydrogen was used in nearly all these cases it might be said that the remedial effect was due to it quite as much as to the acetanilid. Observation has not, however, given me the results with the hydrogen peroxid alone that have compared at all favorably with the simple cleansing and drying of the canal and tympanum with absorbent cotton and the subsequent insufflation of acetanilid. Hydrogen peroxid is employed as a temporary cleansing and antiseptic measure to prepare the suppurating surface for the powdered acetanilid, which acts as a drying agent and also as a valuable antiseptic whose power is exerted so long as it remains upon or adjacent to the surface to be medicated.

A few words in explanation of the details of treatment may not be amiss. First I carefully remove all the discharge that can easily be reached by an applicator with dry absorbent cotton twisted on its end. Then I saturate the same with peroxid of hydrogen, apply this to the auditory canal and tympanum, and after waiting a minute for it to act, carefully wipe out all resulting débris and moisture. Sometimes, having the patient tilt the head to the opposite side, I fill the middle ear and canal with the hydrogen preparation, and after a minute let it run out and carefully wipe the parts dry. By use of the hydrogen peroxid inspissated mucus, pus or cerumen are softened and disintegrated, and the expansive force of the gas generated is sufficient to carry much of the discharge into the external meatus, and even out on to the cheek if not caught by a bit of cotton. I have never had a case in which it found an outlet by the Eustachian tube, choosing rather the easier way of escape.

Syringing the ear for any purpose except to remove foreign bodies or inspissated cerumen is, I believe, a pernicious practice. The middle ear is an air-cavity and does not bear fluids at all well. They irritate the delicate mucous lining, and so do harm. Further, some of the liquid invariably stays behind, and by its presence adds one of the elements that is essential to suppuration, namely moisture. This danger is largely if not entirely avoided by use of the lively peroxid of hydrogen.

As to the use of acetanilid, I would advise that only the most finely powdered be used, and that but little be applied to the middle ear and canal in acute suppuration, and in most cases of chronic suppuration. In some obstinate cases of the latter prompt and permanent checking of the discharge and a desirable condition of the mucous lining of the tympanum is brought about by packing the middle ear and inner fourth of the canal with this drug, but this procedure is unsafe unless the patient is seen every day and carefully watched to guard against retained discharge from caking of the powder. An insufflator may be devised from a short piece of glass tubing and a longer piece of rubber tubing of the same size; or the ordinary powder blowers for sale by instrument dealers serve the purpose well, and to my mind are preferable.

MEDICAL PROGRESS.

A Type of Tropical Fever.—Wedekind (*Med. Record*, August 19, 1899) describes a very common type of tropical fever which prevails in the Philippine Islands and is known to the Spaniards as *calentura*. It attacks a new arrival within a short time. There may or may not be a slight sensation of chilliness and then a temperature of 102° or 103° F. This increases until 104° or 105° F. is reached. Headache, general myalgia, anorexia, and marked asthenia, and gastric disturbances are noted. Without treatment the patient will convalesce in a week. Quinin has no specific effect, whether used in small or large doses. Aconite acts almost as a specific. As soon as the patient is admitted to the hospital he should be given divided and frequent doses of calomel until two or three grains have been taken and afterward a saline purge. Four drops of the tincture of aconite are to be given every three hours for three, four, or five days. An opiate may be required to relieve the pain in the muscles. In the majority of instances the temperature will be normal on the following day and will remain so. After three or four days in bed the asthenic condition will be overcome. Calentura is non-malarial and is apparently due to the direct rays of the sun. Female members of European families who remain under cover during the hot portion of the day escape this fever. Many cases of calentura develop on board ship in men who have not been on shore for many months and while the ships are anchored at least a mile from shore. All drinking-water under these circumstances is distilled aboard ship. Furthermore, protection from the sun's rays by the use of a white umbrella, a large, light helmet, and loose white clothes, will in almost every instance save a new-comer from an attack of the fever. Plasmodia were searched for in the blood of many patients but were never found.

The Results of Bottini's Operation for Prostatic Hypertrophy.—Stockmann (*Rev. de Therapeut.*, July 15, 1899), is an advocate of the more frequent use of Bottini's operation in prostatic hypertrophy. This operation is easily performed and often requires only local anesthesia or at most a very short administration of ether. It does not mutilate the patient. It confines him to bed for a short period only, and yields good results. As is well known, it consists in the introduction of a galvanocautery point of a suitable shape to cauterize the prostate through the ure-

thra. One or more grooves according to circumstances are burned in the hypertrophied gland. In order to assure himself that the cautery-point is sufficiently hot, the writer auscultates the symphysis and is able to learn from the character of the hissing sound produced whether the cauterization is satisfactory. After the cauterization has been made, he uses an irrigation of nitrate of silver, 1 to 1000 The bladder should be emptied before the cautery is applied. Out of seven patients treated by him, 1 was cured, 4 were improved, 1 was unimproved, and 1 died fifteen days later of apoplexy. Statistics of 229 cases collected from medical literature show 51.5 per cent. of recoveries, 26.2 per cent. of improvements, 13.9 per cent. of failures, and 8.2 per cent. of deaths. The rather high mortality is due to the fact that the operation is performed upon patients in an advanced state of cachexia. It goes without saying that the patients described as "cured" have not been relieved of inflammatory complications of the bladder, ureters, pelves of the kidneys or of the kidneys themselves; but it is none the less true that the results of this method of treatment are far superior to those obtained by other methods while it has the especial advantages described above. The chief danger of the operation is the possibility of hemorrhage and urethral fever. In order to avoid this the patient should be examined with the greatest care. The cystoscope should be employed, and a bacteriological examination of urine should be made; and before proceeding to Bottini's operation, an attempt should be made to overcome the prostatic hypertrophy by resection of the vas deferens on each side. If this intervention proves insufficient cauterization of the prostate should be performed.

The Result of the Treatment of Skin Diseases with Tuberculin R.—Napp and Grouven (*Arch. für Dermat. und Syph.*, Bd. xlvi, Hft. 3) report extensive trials of the new tuberculin which have been made in Doutrelepont's clinic for skin diseases. They report 39 cases in detail. The tuberculin was at first injected with normal salt solution, later with water containing 20 per cent. of glycerin. Most of the lesions were covered with moist antiseptic dressings at the same time that the tuberculin treatment was carried out. The general condition of the patients treated with tuberculin varied very much. The fever was of the well-known irregular type. Twice it happened without apparent cause that two strong young men presented severe, indeed alarming, symptoms of cyanosis, dyspnea, collapse, etc. All of the patients lost in weight. Albuminuria was insignificant. One patient developed icterus and cutaneous hemorrhages. The first dose used was as recommended by Koch, but each subsequent dose was about 1-5000 of a milligram greater. The local reaction was only once observed. Histological examination of areas which were apparently much improved showed that tuberculous tissue was still present but that infiltration was much reduced. A number of patients had recurrences after improvement. The authors conclude that tuberculin R. even if it does not produce a permanent cure still has a markedly favorable influence in that it attacks the tubercular process at the same time that it produces, if used with care, no serious disturbance of the general condition. This report is as favorable as any which has been given concerning its use in dermatological cases.

The Full Bath at 90°F. in the Treatment of Scarlatina.—Hanson (*Columbus Med. Jour.*, August 5, 1899), after experimenting with baths at different temperatures, concludes that in the treatment of scarlet fever a bath a 90° F. gives just as good results as one at a lower temperature and that it can be more safely used in asthenic cases and is more comfortable to the child and more agreeable to the attendants than the cold bath. If a bath-tub is not at hand, a large wash-boiler or wash-tub will answer every purpose. The child should be constantly rubbed while in the water in order to effect a rapid change of the blood in the surface of the body. Eight minutes is usually sufficient for the bathing. The child should be dried quickly and put in bed without stopping to put on a night-dress or other clothing. The bath should be repeated whenever the temperature reaches 103° F. or whenever the child becomes restless. The results are even more striking than those obtained with the Brand method in typhoid fever. The good effects consist in a reduction of temperature and a stimulation of elimination and of the circulation. A strengthening of the heart's action relieves the stasis of the skin and internal organs, a change which may be clearly observed by watching the congested conjunctivæ. The repetition of the bath minimizes nerve exhaustion and hastens convalescence. In no case in which Hanson followed this plan of treatment were there any complications or sequelæ. The more he used it the more confident he became of its good results.

Thrombosis of the Superior Mesenteric Vein.—Ballance (*Lancet*, July 3, 1899) reports an instance in which the above-mentioned lesion occurred in a man 68 years of age who had always been accustomed to eat heartily and whose digestion was apparently perfect. For three or four days he felt vague and irregular pains in the abdomen, more on the left side than on the right. While driving one afternoon the pain became more severe. Hot fomentations were applied and he passed a sleepless night. The following day he began to vomit and from that time until his death, two days later, he passed practically nothing from his bowels while vomiting became incessant. The pain and restlessness continued with collapse. The abdomen was not greatly distended. In short, he presented the picture of intestinal obstruction without localized tumefaction or distention. At autopsy the entire length of the small intestine was found dark greenish-black, shiny and distended, presenting the same appearance as small intestine in a strangulated hernia. In the upper part of the superior mesenteric vein there was a pale clot adherent to the walls and completely occluding the vein. The lower part of the vein and all of its radicals contained soft non adherent clots. The splenic vein was not thrombosed. There was no ulceration of the intestine. There was no peritonitis and the cause of the thrombosis was apparently the extreme feebleness of the circulation. The other organs contained a great deal of fat but were otherwise healthy.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 14, 1899.

THE PLAGUE THREATENS US.

In this country slight attention has been given to the bubonic plague and its destructive work among the inhabitants of India and no realizing sense of the danger that threatens us has been aroused. Like a smouldering fire, it has been gathering strength for four consecutive years, repeatedly bursting into flames that have leaped their barriers and ignited combustible material at remote points in divers directions. The Island of Formosa, in the East, Oporto and Lisbon in the west, Samarcand in Turkistan in the north and Delagoa Bay in the south are points of formidable attack from which it threatens with invasion the entire civilized world. Even the fancied security of our own shores, due to their remoteness, vanishes before the vigor of its onward march. The time has come to sound the alarm and awarken our remotest outposts to vigilance, alertness, and activity. These are no idle words. The British Empire has already been arraigned for its lack of vigilance and activity in failing to stamp out the disease at its inception. Europe has been derelict in allowing it to gain a foothold within her borders, and the responsibility of those who are charged with the duty of preventing its admission within our boundaries is great beyond measure. In the minds of many, Europe has stood as a reliable barrier between us and the bubonic plague, but now that this defense has been broken through in many places, the responsibility for our safety comes back upon ourselves.

Accurate scientific knowledge of this disease is steadily increasing, but as yet no specific remedy has been discovered, and a victim to its invasion must depend for relief mainly upon his inherent powers of resistance and the most scientific harboring of his strength by means of careful nursing. A serum has been produced which, as careful experimentation shows, renders immune a certain proportion of those who have been inoculated, and diminishes to a limited degree the death-rate among those attacked, but as yet its efficacy is not sufficient to warrant any guarantee of its power. The only sure safety lies in not coming within the range of the plague's infectious influence; in other words, in quarantine.

The plague goes hand in hand with famine, and just now finds a favorable ally in the failure of the crops in India. The disease itself is, therefore, taking on new vigor in its original haunts. In the Bombay Presidency alone it is slaughtering its victims at the rate of 2300 per week, and in August last it had already claimed a grand total of 164,083 deaths. There has occurred also recently a recrudescence of the disease at Alexandria, at Samarcand, and in the Island of Formosa. During the last few months it has followed the lines of commerce in various directions and spread over a wide territory. In addition to Hong Kong, it has invaded three important posts in China, and an equal number in Japan. It has crossed the Indian Ocean to the islands of Mauritius and Mozambique, and has also reached the East African coast at Delagoa Bay and the French Ivory Coast Colony. It has reached Busliore in Persia, Djiddah in Arabia, Kolobovka in Astrachan on its way to Russia, and even been carried to St. Petersburgh, where two cases have been reported, while the points nearest to us that have been infected are Oporto and Lisbon in Portugal. With its appearance at a locality on the Persian Gulf and at Kolobovka in Astrachan, a a direct route is opening through the Ottoman Em-

pire for invasion of Europe along that most dreaded line of traffic. This recrudescence demonstrates that the disease has gained not lost in virulence and in epidemic power.

The widespread invasion proves conclusively that existing quarantines are inefficient. The characteristic cycles through which the disease passes in its complete development, render it a most treacherous foe. Its initial period is characterized by slight virulence, rendering it difficult of recognition; then follows a serious outbreak with great fatality; then a period of subsidence invariably followed by renewed virulence and fatal activity. Ten days has been set as the limit of incubation, but it is recognized now that the bacilli may be carried in various ways, as under the finger-nails, and for even a longer period before inoculation, and the duration of quarantine therefore remains indefinite and insecure.

It is hardly time to speculate upon what direful havoc would be wrought among the slum and tenement-house population of our great cities, and the negroes of the South if once this insidious disease should pass our borders. Of the possibility that it may reach our shores at any day there is no doubt. Our safety lies in meeting it at our maritime quarantine with certainty, with unflinching firmness, and most destructive methods. That the members of the Marine Hospital Service and other quarantine officials are alive to the situation is evinced by the fact that some of their most expert diagnosticians have gone abroad to meet the invasion at various points of its approach, to become familiar with the symptoms of the disease, and to insist upon proper inspection of all merchandise destined for these shores.

THE BRITISH EMPIRE RESPONSIBLE FOR THE PLAGUE.

In a letter to the *British Medical Journal* of September 16, 1899, Dr. Wilfred Watkins-Patchford, late Special Plague Medical Officer in the English Service, and author of the Report on Antiseptics issued at Bombay last year, makes the following rather startling protest against the position that has been taken by the British Government in India with regard to the study of plague and the investigation of the best means for its prevention:

> The unique opportunity afforded to the Indian Government of systematic research into the disease by scientists of accredited standing has been neglected. I unhesitatingly affirm that scientific research into the plague has not been in any way encouraged by the authorities; the problem has been dealt with on the lines of a civil misfortune to our Indian dependency, while the momentous interest which the disease has for the whole human race has been left to the consideration of a few private individuals.

The accusation is so serious a one that we have waited for the succeeding issues of the English medical journals before commenting on it. It seemed almost a foregone conclusion that some attempt at least would be made to explain away the serious negligence on the part of the British Indian authorities, so frankly put in accusation by one who, it is to be presumed, is in a position to know. The explanation has not been forthcoming. A feeling has been growing in the medical world for some time that the plague might have been kept more thoroughly under control in the East if the British Government in India had been more ready to use all the resources that modern hygiene and sanitation had placed at its command. The civilized world has a right to demand that the British authorities in India shall omit nothing that can help to lessen the continual danger from the plague, which has now become a continual, harassing threat.

We realize the difficulties of the situation, and have called attention in our columns more than once to how seriously the Government's attempts at enforcement of sanitary measures are hampered by the ignorance, and still more by the religious fanaticism of the people. We cannot help thinking, however, that the existence of plague in India has come to be looked upon by the British authorities in India too much as a matter of course.

There is "the white man's burden" to bear for the world in this matter, and no routine regulations or ordinary methods a little more strictly applied will suffice for this serious juncture. Special measures and special men are required. Sporadic efforts at times of awful mortality, to be intermitted when the well known remissions of plague virulence occur, will never suffice. Portugal has been seriously arraigned because plague existed in that country for nearly two months before its official announcement. We fear that there would be many and more serious faults than this to be laid at the door of the British Indian Government if the details were but known.

What Dr. Watkins-Patchford demands by implication must be insisted upon by civilized nations. The problem must not be dealt with merely on the lines of a civil misfortune to the Indian dependency, but England must realize the momentous interest which the disease has for the whole human race, and her plans for its complete eradication must be on a corresponding scale. The British Empire owes this to herself if she is to justify her mission to the world as the great civilizer and fosterer of progress.

THE NEWER THERAPY OF GONORRHEA.

It was the discovery of the specific organism of the disease by Neisser two decades ago and its subsequent more elaborate exploitation by Bumm that gave an important impetus to the study of the course and effects of gonorrhea. The medical mind was slowly forced to a realization that perhaps this malady, which in spite of its distressing nature had always been regarded as a matter of merely passing interest and to be treated lightly in a quasi-jocular way, might be a much more serious thing than had been supposed, and this uneasy suspicion was gradually succeeded by the absolute conviction that for gravity of consequences and variety of possible sequelæ its capacity was almost unlimited. And when the gynecologists took up the cry and denounced the infection as a two-edged sword which often cut deepest in innocent flesh, and after the lapse of years could produce in an unsuspecting wife consequences out of all proportion to the initial severity of the trouble in a long-ago erring husband, the full import of the situation was recognized and the time-honored methods of treatment began to be abandoned and search made for surer and more definite remedies. The synthetic chemist has not been slow to respond to the demand, and the last half dozen years have seen produced and extravagantly advertised as many so-called specifics—kaleidoscopic combinations each of them, in which silver is the central and active constituent, surrounded by picturesque graphic formulæ of albumins, nucleoproteids, diethylamins, etc., added with the object of diminishing its irritating properties and increasing its penetrating power.

Kopp of Munich (*Münchener Medicinische Wochenschrift*, August 1 and 8, 1899) presents a careful comparative analysis of the most important of these preparations and though the observations of a single investigator are never conclusive, especial importance attaches itself to his results inasmuch as they were obtained from perfectly fresh first attacks and exclusively from private patients, in whom it was possible to follow definite lines of treatment with exactness, rather than from dispensary patients, notoriously hard to control.

Argentamin (ethelyndiamin silver phosphate) was found to be markedly irritating even in solutions of a strength of 1 to 4000; decidedly more so than the usual silver nitrate solutions. No permanent disappearance of the gonococcus could be effected and no cures resulted from its unaided use. A growing toleration for it, permitting its application in more concentrated form, was not observed.

Argonin (silver casein). Although less irritating than silver nitrate, in most cases it is inferior to the latter in efficacy. Up to a strength of four per cent. it usually does not irritate though sometimes even two-per-cent. solutions cause symptoms requiring its abandonment. Its expense also is against it, and its sphere of usefulness seems to be limited to those cases in which it is essential to avoid irritation as much as possible and in which the use of silver nitrate, therefore, is not permissible.

Protargol (silver protein). Considerable confusion has arisen as to the merits of this preparation, owing to the fact that prior to June, 1898, samples of varying composition and strength were on the market. Since then the character of the remedy has been constant. Its use presents the feature, agreeable to the patient, of causing little irritation and a rather speedy checking of the discharge, though the discomfort attending the daily thirty-minute injections recommended by Neisser perhaps more than offsets these factors. On the whole it presents no decided advantages over silver nitrate.

Largin (silver protalbin). Although distinctly not to be considered as an abortive, still the use of this drug in the early stages of the infection seems to shorten its duration. Usually it irritates about as much as silver nitrate, and possesses no marked superiority over it.

Itrol (silver citrate). This preparation, so strongly advocated by Crede, seems to possess real merits. Its cheapness and the dilution of the solu-

tions employed (0.05 to 200) are in its favor; its disadvatages are the difficulty of preparing aqueous solutions and the rapidity with which these decompose. It is also much commended as having great pen etrating power though the extent to which this is true is probably more limited than is generally supposed. Its undoubtedly strong bactericidal powers, however, and the fact that complications such as posterior urethritis, etc., seem to occur but seldom with its use are sufficient grounds for recommending it to a prominent place in gonorrheal therapy.

Hydrargyrum oxycyanatum. The urethral mucous membrane evinces a considerable toleration for this reagent, solutions of 1 to 3000 or 1 to 1000 having produced no unpleasant results. In general it resembles protargal in its action and has no greater claims to specificity than its predecessors.

Janet's irrigation method with potassium permanganate has proved disappointing, in the author's hands, both as an abortive agent and in the treatment of the acute form of the disease. In chronic and posterior urethritis, however, it is most valuable and satisfactory; if gonococci were still present in the secretion silver nitrate, 0.2–0.5 to 1000, was used; after their disappearance potassium permanganate, 0.3 to 1000.

In short, it appears that though these various preparations may each have specific points of excellence, none of them can be designated as a specific for the disease; and though some, especially protargol, itrol, and the oxycyanate of mercury, are distinctly less irritating than silver nitrate they do not seem destined to drive that hardworked reagent from urethral fields.

Although to the eye of the stern moralist the dread of a possible infection presents a most potent incentive to continence, still under existing social conditions, and in dealing with a malady so far reaching in its consequences as this no means of restricting its spread should be neglected. Indeed it is quite worthy of belief that the universal dissemination among the laity of the fact that a few drops of a twenty-per-cent. solution of protargol in glycerin, instilled into the fossa navicularis after a suspected coitus, will secure almost perfect immunity from infection would react only in a beneficial manner on the welfare of the race. It is at least an experiment well worth the trial.

ECHOES AND NEWS.

Women Physicians in England.—In London and the provinces there are no fewer than thirty-seven institutions officered wholly or partially by women physicians.

Dr. Clark Appointed Professor of Gynecology in the University of Pennsylvania.—Dr. John G. Clark, formerly of Johns Hopkins University, has been appointed professor of gynecology in the University of Pennsylvania, to succeed Dr. Charles B. Penrose, who resigned at the close of the last term.

A Doctor's Bequest to the Harvard Medical School.—It is announced that Dr. Galvin Ellis, Harvard class of '46, who died in 1883, and whose will has just been probated, left to Harvard University $140,000. Most of this sum is to be devoted to the education of his descendants, and also to the maintaining of three professors at the Medical School.

Inspection of Immigrants.—Dr. Doty of the Quarantine Station in New York harbor sailed for Europe on October 10th to consult with foreign officials, chiefly at Bremen, concerning an improvement in the present methods of excluding, at the point of embarkation, emigrants who are infected with smallpox, typhus, or typhoid fever.

The Rat-trap as a Plague Cure.—According to a despatch from London, considerable attention was attracted to the recent meeting of the School of Tropical Medicine, at which Dr. Manson declared that cholera is waterborne, malaria mosquito borne, and the plague rat borne, and tersely defined preventives against these scourges to be "tea-kettle, mosquito-net, and rat-trap."

Larkspur Poisoning —Two women, who were patients at the Loretto Home, New York City, died on October 7th of larkspur poisoning. The drug was in solution in wood alcohol for the purpose of destroying vermin. These unfortunate women came under treatment to be cured of alcoholism. They drank the solution because it smelled of alcohol and without any knowledge that it was poisonous.

Bowdoin's Clinical Work at Portland.—Of special interest, because it is the second important medical school that is to have its theoretic and its practical teaching in different places, is the following announcement from the faculty of Bowdoin Medical College: The medical students of Bowdoin College will receive instruction during their last year at Portland, where suitable buildings are now be ng erected, and where they will have improved clinical facilities. After 1900 the course will be four years in length, the first two years being spent at Brunswick, and the second two years at Portland.

Jews Aid a Catholic Hospital.—St. Vincent's Hospital, a Catholic institution situated at Norfolk, Va., was burned recently, and several lives were lost in the fire. Money

to aid in rebuilding the hospital is being raised by popular subscription. The Ladies' Hebrew Benevolent Association of Norfolk contributed $100. This incident is not unlike one which occurred several years ago in this city. A Presbyterian church in Twenty-third street was burned down. The use of the beautiful Synagogue at Forty-third street and Fifth avenue was offered this congregation. The offer was gratefully accepted, and for many Sundays these Christians worshiped there. Truly, if the world is not growing better it is at least becoming more tolerant.

A New Medical Directory.—"The Medical Directory of New York, New Jersey, and Connecticut for 1899," edited by Dr. E. Eliot Harris, under the auspices of the New York County Medical Association, has just made its appearance. It is a handsome volume of nearly 900 pages, and contains the names of 19,161 registered physicians, dentists, and pharmacists, in addition to the by-laws of the Medical Associations and Societies of the three States named, and the laws relating the practice of Medicine, Dentistry, and Pharmacy, including the New York Dispensary Law. The book reflects great credit upon those having its publication in charge. Copies may be obtained from Dr. O. C. Ludlow, 2309 Seventh avenue, New York City, at $2 each.

"Divine Healer" to Blame. — Dowie, the "Divine Healer," Christian Scientists, and all others of that ilk, are held responsible by Chief Inspector Herman Spalding of the Health Department of Chicago for the present prevalence of scarlet fever and diphtheria among the school children of that city. "When we are notified," said he, "of a case of this character we can handle it without any great trouble, but when it is kept secret it is impossible to tell what the result will be and where it will end. The peculiar belief that teaches us to close our eyes and call upon the Lord to do the work of the doctor and sanitarian has helped ignorant parents in the work of spreading preventable contagious diseases. The beauties of this method of treatment are to be found only in the wealth of flowers placed upon little graves."

The Yellow-Fever Situation is decidedly improved. The cold weather at the beginning of last week seemingly destroyed to a large extent the contagiousness of the germs of the disease. At the end of last week one new case was reported in New Orleans and there were no deaths from the disease. There was a slight recrudescence of the disease at the beginning of the present week, two new cases having occurred on Sunday and two more on Monday. The fever is very mild in form. As we go to press some ten patients in all are under treatment in that city. In Key West, while the improvement was not so radical as in the Mississippi region because the cold had not been so noticeable, there was a marked falling off in the incidence of the disease, less than half as many cases per day being reported as during the previous week. The disease retains its mild, non-fatal character and the number of deaths is less than 12 per cent. of the new cases reported. It is believed by the sanitary authorities now that the end of the epidemic is in sight.

A Hotel Syndicate and a Scientific Association.—*Science* is our authority for the following statement. According to certain letters that appeared in the London *Times* shortly after the recent meeting of the British Association for the Advancement of Science at Dover, it appears that an English Syndicate engaged in advance all the hotel accommodations in Dover for the week of the meeting and relet them to members of the Association at extortionate rates. Verily our English cousins are advancing in the ways of this world. Suppose something like this should happen in America what a virtuous howl of indignation would it not be greeted with? What diatribes would we not have on the contemptibly sordid commercial spirit that has invaded everything American? There is a lesson in it all for scientific societies and especially medical societies since they meet so frequently and their meetings are as a rule so well attended. It would seem to read about as follows: Do not accept invitations from the smaller towns, unless assurance is given that the presence of so many members shall not be made the opportunity to exploit them by the unsympathetic townspeople.

The Scientific Spirit —The excellent paper which Sir Michael Foster, the president of the British Medical Association, read on September 13th, on the occasion of the visit of the members of the French Academy of Sciences at Dover, contained the following passage: "As I have already urged, no feature of scientific inquiry is more marked than the dependence of each step forward on other steps which have been made before. The man of science cannot sit by himself in his own cave weaving out results by his own efforts, unaided by others, heedless of what others have done and are doing. He is but a bit of a great system, a joint in a great machine, and he can only work aright when he is in due touch with his fellow-workers. If his labor is to be what it ought to be, and is to have the weight which it ought to have, he must know what is being done, not by himself, but by others, and by others not of his own land and speaking his tongue only, but also of other lands and of other speech. Hence it comes about that to the man of science the barriers of manners and of speech which pen men into nations become more and more unreal and indistinct. He recognizes his fellow-worker, wherever he may live and whatever tongue he may speak, as one who is pushing forward shoulder to shoulder with him toward a common goal, as one whom he is helping and who is helping him. The touch of science makes the whole world kin."

The Improvement of Havana.—On this subject the *Scientific American* said editorially last week: "General Ludlow's report as commander of the Department of Havana, and as military governor of the city of Havana, covers the period of our occupation up to September 5th. It shows that the problem of reorganizing the government of Havana and the uplifting of the city from the filth and neglect in which the Spaniards left it, has been

taken in hand with characteristic system, energy and thoroughness. The physical condition of the city at the time of the Spanish exodus was simply shocking. Starvation and death were matters of every-day occurrence. Neglect of the most common sanitary precautions had raised the death-rate to alarming figures, which exceeded greatly the all too heavy prevailing death-rate of the city; and the inevitable restlessness and lawlessness following the removal of the Spanish troops were everywhere conspicuous. While much remains to be done and many problems are awaiting solution, there is just cause for congratulation from the fact that the death rate, for instance, in June, July, and August was lower than the average for the same months during the past nine years, not even excluding the two calamitous years of the war, 1897 and 1898; while the indications are that the total number of deaths for the current year will be only half the number during 1898. The deaths per month during 1898 were only 162, which is the lowest since 1890."

Female Army Nurses Wanted. — Dr. Anita McGee, United States Army, is at present visiting Mrs. Mary H. Willard, the president of the Metropolitan Trained Nurses' Club at 104 West Forty-first street, and is anxious to meet and talk to any one who wants to be an army nurse. Dr. McGee states that since the beginning of the war there have been 1700 nurses in the service. There are now 200 in the service and 200 on the waiting list. Army nurses, who must be graduates of regular training-schools, have their living and traveling expenses paid, a yearly thirty days' furlough, and when assigned to duty in this country $40 a month and when assigned to duty elsewhere $50 a month. These salaries include lodging and rations. Each nurse wears a beautiful uniform, a description of which is beyond the writer's capabilities. There is a chief nurse for each hospital, whose pay depends upon the number of nurses under her. If less than ten, she gets $10 a month extra. If more than ten her wages are increased $25 a month. The nurses are assisted in their work by the men of the hospital corps, who are not trained nurses. A new hospital, states Dr. McGee, is building at Manila, which will be the largest army hospital owned by the United States. It will accommodate 2000 persons. The hospital used at present was meant to take care of 500 sick and wounded soldiers, but there are now more than 1500 in it. It is in charge of Surgeon General Woodhull, to whom Dr. McGee accords high praise. Our next largest hospital is at Presidio at San Francisco, which will accommodate 1000 persons.

Supreme Court Decision as to Medical Consultants. — A decision rendered October 4th on this subject by the Appellate Term of the Supreme Court of New York State is of special interest since it reopens a case. A lady stopping at a hotel having suffered an accident to her elbow, the physician usually summoned by the hotel manager was called to treat her. He was unknown to both the lady and her husband, but was permitted to remain in charge of the case. He summoned a consultant who came altogether six times. The bill of the hotel physician was $70, that of the consultant $175. The patient's husband refused to pay and on suit judgment for the amount was given against him in the Municipal Court. He carried the suit to the Supreme Court. A reversal was directed by the Appellate Term, in an opinion per curiam, Presiding Justice Freedman and Justice Leventritt stating that justice would be best promoted by a retrial, "so that the proof of the value of the services of the plaintiff and of the consulting surgeon might be more clearly established." Justice McLean also gave an opinion in favor of reversal, saying in conclusion: "There was no justification by custom or otherwise in plaintiff's employment of a consultant without a frank and full statement of the situation to the patient and the defendant, and learning their wishes concerning the professional persons to be brought in. There cannot be properly applied to the facts shown here any custom multiplying ordinary professional charges five or ten times under the shield of a layman's ignorance, because it is subversive of justice that charges should be so largely increased by a custom not made known at all to the patient or to her husband."

The whole matter would seem to be the result of a real or pretended misunderstanding on the part of the defendant of the status of a consultant in a case of this kind. It would be interesting to see with what short shrift a similar case involving a legal consultant would be disposed of by their honors.

The Plague Situation generally is about as it was, certainly no better. Though the daily papers have ceased entirely their reports as to the matter, and popular interest in it in other countries has died out, the plague still continues to be mildly epidemic at Oporto. About a dozen cases occurred during the last week in September. Altogether about 100 cases with about 40 deaths have occurred in Portugal. After the recent fall in the temperature the number of cases increased. The rumor that cases of the disease have occurred in other parts of the Peninsula is denied. Arrangements have been made to allow the factories to begin work again, and their manufactures will be permitted to leave Oporto after a careful disinfection. The favorable report as to the effect of Yersin's plague serum that we quoted last week has been confirmed by further experience. No deaths have occurred in any cases that were treated with the serum, though the death-rate has been, as noted above, about forty per cent. during the epidemic. The situation in India is not very reassuring. We clip the following notes from the last issue of the *British Medical Journal*: "In the city of Bombay eighty-nine deaths from plague occurred during the week, September 19th. Throughout the Bombay Presidency the numbers show little change. The last news from Poona was to the effect that a sudden drop in the number of plague cases had occurred, and, from being at the rate of over 100 cases a day, the number fell to *nil* within a week. This week the report is that the condition of affairs in Poona and district has much improved, but, on the other hand, plague is stated to be increasing among Europeans. This is but a repetition of the history of plague in every town; during the first outbreak it is quite exceptional for plague to attack Europeans, but during a recurrence Europeans contract

plague in increased numbers, although in no Asiatic city have they suffered severely. Forty-four deaths from plague occurred in Calcutta during the week ending September 19th. Calcutta affords perhaps the best example of the occurrence of plague in a chronic as contrasted with the epidemic form. There has been no scaring epidemic of plague in Calcutta, but for well-nigh eighteen months deaths from plague have persistently occurred." The report that plague was occurring in Portuguese East Africa is confirmed. The news comes from Lourenco Marques, a town that, owing to the shipments of munitions of war to the Boers, has become well known through the daily press. Twelve cases believed to be plague have occurred at Magude, a suburb of Lourenco, and two of them were fatal. The village of Pombacas has been isolated and many dwellings burned. From Russia a note of alarm is once more sounded. Prince Alexander of Oldenburg, president of the Plague Commission, has recommended the municipal authorities to establish night camps and huts capable of accommodating 1000 persons in view of the outbreak of plague. We reported the occurrence of some cases in Turkey in Asia last week, and now it is announced that the whole of the Syrian coast has been placed under quarantine because of reported cases of the disease in the seaports. With regard to Asuncion, Paraquay we clip the following from the *British Medical Journal* for September 30, 1899, as we have no definite details of later date: "The sanitary authorities of Montevideo, Uruguay have received a report from the special commissioners sent to Paraguay to investigate the reported outbreak of plague in Asuncion, to the effect that 'the symptoms displayed in the cases in question confirm beyond all doubt the suspicions entertained as to the character of the disease. We presume that, in the belief of the commissioners, plague does exist at Asuncion. As this is the first time plague has ever visited America, and as the isolated spot in which it has developed is some 600 miles from the sea coast, we must still hesitate to accept the existence of plague there as being conclusively proven."

MEDICAL MATTERS IN PHILADELPHIA.

MEETING OF THE COLLEGE OF PHYSICIANS—ARTERIOVENOUS ANEURISM OF SCARPA'S TRIANGLE—ESTATE OF THE LATE DR. WILLIAM PEPPER—HOSPITAL OF THE MEDICAL EMERGENCY CORPS—ANTICIPATING ANOTHER SMALLPOX EPIDEMIC—OPENING EXERCISES OF JEFFERSON MEDICAL COLLEGE, THE MEDICAL DEPARTMENT OF THE UNIVERSITY, AND OF THE MEDICO-CHIRURGICAL COLLEGE—DR. ASHTON APPOINTED PROFESSOR OF MEDICINE.

PHILADELPHIA, October 9, 1899.

AMONG the papers read at the first fall meeting of the College of Physicians of Philadelphia, was an interesting communication on the subject of "Arteriovenous Aneurism of Scarpa's Triangle," presented by Dr. W. Joseph Hearn. A brief abstract of the history of the case is as follows: The patient, a well-developed negro, of forty years, and presumably without a previous history of syphilitic infection, began five months ago to notice the presence of a small growth about the size of an English walnut in the central portion of Scarpa's left triangle; the tumor rapidly increased in size, until at the time of the operation it had attained approximately the size of a large cocoanut, and was the cause of much suffering and discomfort to the patient. The tumor was felt below the skin as a somewhat conical, smooth, elastic mass, distinctly pulsating with each heartbeat, and being the seat of a plainly audible bruit. No pulsation of the vessels of the leg below the tumor could be detected. The first step in the operative procedure was the ligation of the external iliac artery through Abernethy's incision. An effort to expose the femoral below the site of the tumor was then made, but temporarily abandoned. The tumor was then incised, and a large quantity of blood turned out, severe hemorrhage ensuing from the bottom of the cavity thus opened. This bleeding was controlled temporarily by firmly packing with gauze, but again recurred on the removal of the packing, the second hemorrhage being finally controlled by digital pressure both above and below the cavity. The artery was then ligated at two points, above and below the site of the hemorrhage, and the femoral ligated in Hunter's canal. Bleeding still continued, and on removal of the remains of the aneurismal sac the vein was seen to open into it, so it became necessary now to ligate the femoral vein above and below the point of bleeding, in order to control the hemorrhage. The wound was drained with iodoform gauze, and closed with silkworm-gut sutures. The hemorrhage, during the operation, became so alarming that it was necessary to give the patient intravenous transfusions of normal saline solution to the extent of three pints of the fluid. The patient made an uninterrupted recovery, and was discharged from the hospital, cured, within seven weeks after the operation.

Concerning the etiology of the condition in this case, Dr. Hearn remarked that the only causal factor appeared to be the nature of the man's occupation. The patient, a carter, in loading his cart with earth, had always been in the habit of using a short-handled spade, the handle of which he habitually pressed against his thigh over Scarpa's left space, to drive the blade of the tool forcibly into the earth. Often he was compelled to exert the entire weight of his body in accomplishing this, so that continual and forcible pressure over the situation of the tumor was made for a long period. The speaker considered that the cause of the involvement of the vein in the aneurism was not the traumatism, but rather that it was due to erosion of the walls of the vein from pressure by the distended sac of the aneurism, and to inflammatory exudate matting together the walls of the vein and the sac of the tumor. Dr. Hearn expressed the view that the ligation of large vessels for aneurism is not to be usually considered as fatal an operation as generally thought—in his hands it had been uniformly successful, he never having had a death, which might have been partly due, he said, to the fact that his experience in these operations had been limited to the days of antiseptic surgery. The point of chief interest in this case is that the collateral circulation was sufficient to prevent gangrene of

the limb, notwithstanding the fact that both artery and vein were ligated above and below Scarpa's space. In conclusion, the speaker expressed his preference for the use of silk ligatures in such cases, having always employed this material to the exclusion of catgut.

The first account of the estate of the late Dr. William Pepper has been filed by his executors and trustees. The total value of the estate amounts to more than three-quarters of a million dollars. It will be recalled that Dr. Pepper devised $75,000 to the University of Pennsylvania as an endowment fund to the William Pepper Clinical Laboratory.

The Philadelphia Medical Emergency Corps has opened a hospital on the grounds of the National Export Exposition, the building being situated in a prominent part of the main avenue, and is admirably adapted for the purposes it is intended to fill—the treatment of medical and surgical emergency cases occurring among visitors to the exposition. There are two large rooms for patients; one, a ward of four beds; the other, an operating-room and dispensary, and a drug-store. A bicycle-ambulance is to be added to the equipment of the hospital in a few days.

The Department of Public Safety, through its chief, Director English, has requested from Councils an appropriation of $25,000, to be used for repairs and additions to the Municipal Hospital. The authorities assert that they anticipate another smallpox epidemic this winter, and that in its present condition of ill-repair and of antiquated equipment it will be impossible to properly house and care for the victims at the Municipal Hospital.

Under the most auspicious circumstances, in the presence of a large and distinguished audience the new college buildings of the Jefferson Medical College were formally opened and dedicated on the evening of Tuesday, October 2d. The opening exercises were held in the large amphitheater in the new Walnut street building, the proceedings of the evening being of the character of an ovation, in celebration of the completion of the new laboratories and college buildings.

The exercises were opened by a short address by the President of the Board of Trustees, Ex-Minister to Italy William Potter, who reviewed the recent improvements made at the institution, and spoke of future changes which he hoped the friends of the college would, by their generous aid, make possible. At the conclusion of his address, Mr. Potter introduced the presiding officer of the evening, Dr. Thomas Addis Emmet of New York, of the class of '50. After the opening prayer by the Rev. J. Andrews Harris, D.D., Dr. Phineas L. Connor of Cincinnati was introduced, and made the principal address of the evening.

Dr. Connor, in opening, remarked that "The years of Jefferson cover more than one-half the period in which there has been collegiate training in America, and when, in 1825, McClellan, Eberle, Smith, and their colleagues began their labors, medical teaching in the few existing schools was hardly other than supplementary to private instruction in the offices of preceptors. Prior to 1813 there were but two medical schools in New England, four in the Middle States, and not one south of the Potomac, or west of the Alleghanies."

In conclusion the speaker referred to the ideal methods of clinical training now in vogue in all metropolitan teaching-hospitals, spoke of the attitude of kindness and sympathy which the student should uniformly bear toward suffering humanity, and invoked the personal influence of every undergraduate present to continue in the good work pursued by Jefferson graduates during the last three-quarters of a century.

Surgeon-General Sternberg, United States Army, was then introduced, and made a brief address dealing with the pioneer days of bacteriology, and of the wonderful practical advances made during recent years in this branch of medicine. He then spent an interesting fifteen minutes in the discussion of the peculiar advantages enjoyed by the present commissioned medical officers of the army, as compared to their predecessors thirty years ago.

At the conclusion of the exercises the guests of the evening were shown through the various departments of the new college building, following which a reception to the alumni was held in the library. Early in the evening President Potter gave a dinner at the University Club to the distinguished guests, among whom may be mentioned Surgeon-General Sternberg, Drs. Connor and Emmet, Provost Harrison of the University of Pennsylvania, Talcott Williams, LL.D., and Mayor Ashbridge.

The opening exercises for the session of 1899–1900 of the Medical Department of the University of Pennsylvania was held October 2d, in conjunction with those of the Department of Dentistry and of Veterinary Medicine. Provost Harrison delivered the introductory address, and the deans of the various departments delivered addresses to their respective classes of students.

The session of 1899-1900 of the Medico-Chirurgical College began October 2d, the opening address being delivered by Dr. John V. Shoemaker. An address on "Reform in Medical Education" was also delivered by Dr. Charles W. Burr.

Dr. Thomas G. Ashton has been appointed clinical professor of medicine in the Woman's Medical College of Pennsylvania.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

MESMERIC HEALER IN LONDON—SPLIT IN THE "PECULIAR PEOPLE"—JEWISH MUNIFICENCE TO HOSPITALS—FOOD POISONING AT ALDERSHOT—FATAL FALL OF A SOMNAMBULIST—MEDICAL VOLUNTEERS FOR THE TRANSVAAL—DOCTORS AND NURSES FOR PLAGUE DUTY IN INDIA—AN "ELECTRIC RETINA"—A MEDICAL PRESIDENT-ELECT FOR THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE—DOCTORS AND UNDERTAKERS AGAIN.

LONDON, October 1, 1899.

WE speak of the age of superstition as over and gone, but if we want to get a whiff of the Dark Ages, all we need do is to step into the air of a sick-room. A "mesmeric healer" has been here the past few weeks in full

blast in a fashionable street and attracting the most distinguished personages. The magic of his eye is all the remedy employed by him and he accepts no fees for his services but—there is a plate at the door where grateful patients may relieve their feelings in cash deposits. These fleecers know their dupes to the very tails of their P's and Q's. Any one who is fool enough to believe that he can be cured by the glance of an eye is ready to believe that he could be blighted by the same agency and he will deposit liberally against such a contingency. To think of evading the law against unqualified practitioners and making your patients "sure pay" at one stroke! It takes genius to be a sharper and if we honest men don't succeed, it's not because we're honest but because we're stupid. We'd make no better success as rogues, although we love to console ourselves with the thought that we would.

On the other hand, a cheering ray of progress and common sense breaks through the fog of superstition where we least expect it. Those "Peculiar People" who killed Harold Frederic, with his own able assistance, and who are continually vexing the souls of the judges by appearing to answer to a charge of manslaughter for letting a child die, are about to reduce their already small numbers by a "split in the church." One of their leading elders named Grey, in a lucid interval was recently guilty of the heinous offense of calling in a physician to relieve the sufferings of his child. For this lapse into sin he was promptly "dealt with," but stiffened his neck and said he'd do it again under the circumstances and the church might go hang. Whereupon nearly half the church endorsed his sentiments and now each half is trying to turn the other out. Even religious convictions can't quite waterproof men's brains against common sense and decency nowadays and this body of Peculiar People (long may they remain so by contrast!) are now doing openly and clumsily what the Christian Scientists have been doing privately and with artistic mendacity for ten years past. Their faith is so pure and high that they must relapse from it occasionally to keep in touch with it at all and each time is to be the last and "don't count" like Rip Van Winkle's dram.

It is a happy and appropriate coincidence and typical of a most prominent side of the Jewish character that just as one half of the civilized world is denouncing and abusing the Hebrew, one of the West of England hospitals should be presenting to a Jewish baronet, Sir Massey Lopes, his portrait painted in oils, as a memorial of long-continued service to the hospital, and gifts to the amount of nearly $100,000. Among all the numerous things that may be said for and against the Hebrew, the medical profession has nothing but good to contribute. In whatever other respects he may be lacking, he is never so when the call comes from the sick and afflicted. To his own people he is kindness itself but his charity is far indeed from ending there and when a new ward is to be built, or a hospital deficit met, we medical men well know that in their direction one may turn with certainty of a generous response. Scarcely a Jewish community of five hundred souls is to be found in any of our English or American cities which does not count among its members a man of the type of Moses Montefiore and Baron Hirsch! Men who would fight a business deal down to the last fraction of a cent, "upon instinct," simply because they couldn't help it, they must play the great game in its full rigor, but whose purse-strings are slackened at once to the cry of destitution or suffering.

Some forty soldiers at Aldershot have been suffering from a severe form of food-poisoning which culminated in the death of one of them. The attack is believed to be due to some canned fish, sardines and salmon, which the men had purchased at canteen and of the licensed vendors about the camp. The precise brand of goods has not yet been identified but the military authorities have issued a rather sweeping and "shot-gun" order prohibiting the sale of any canned goods whatever at these stands or of any pies not baked in the camp kitchens.

One hears so much of the curious old belief that sleep-walkers can come to no harm during their somnambulistic vagaries, no matter how dangerous the places they may venture into, that a clear proof to the contrary is not without interest. An inquest has just been held upon the body of an unfortunate soldier, who, while walking in his sleep is believed to have found his way out on to the roof of the barracks. Next morning he was found in the barrack square with a fractured skull and spine and died in in a few hours.

The strong feeling in regard to impending trouble in the Transvaal is affecting even the medical profession. The surgeons attached to the volunteer regiments, corresponding to our militia, have been approached by the Government with reference to their willingness to enlist for service in South Africa in the event of war. It is stated that a majority of them have replied in the affirmative.

So obstinately does the bubonic plague hang on in Bombay that the India Office has just secured and is about to send out a fresh detachment of twenty physicians and thirty nurses for plague duty in India. Many of these though young have seen plague service before and so go thoroughly forewarned and prepared to do the best possible both for others and for themselves.

A good deal of attention is being devoted in the lay press here to the claims of an alleged Russian scientist, Dr. Stiens, to furnish sight to the blind by electricity. We have learned through numerous experiences to be distinctly suspicious of the wonders which are proposed to be wrought for the ailing simply "by electricity." This bright force is a sort of modern philosopher's stone and its name a word to conjure with, to the multitude. Stiens does not condescend to give any details or explanations of principle, whatever, which is not reassuring, but merely states that he can by passing a certain current through a man produce in him a sort of "electric eye," through which the *brain can perceive the light rays directly* without any further need of either retina or optic nerve. How this is done is as yet a mystery, also whether it is done at all or not. Several guileless reporters have been blindfolded and then made to see objects through the bandages and through wooden

screens or say they have, and one newspaper scientist is sure the X-rays are at the bottom, because they can penetrate linen bandages, forgetting that the retina cannot perceive them in any case. There is, of course, a bare possibility of truth about the claim, inasmuch as the light-rays which fall upon the retina are transmuted in some way for transmission to the brain, possibly into some electrical equivalent. At all events they do not pass along the optic nerve as light-rays, and if M. Steins' apparatus can transmute the light-rays into their optic-nerve equivalents, then it may be possible to see without a retina. But it is a *very* large "if."

It really looks as if medical men were beginning to get their fair share of honors, scientific ones at least. Here are three members of the profession in succession in the presidential chair of the British Association for the Advancement of Science with only a year between. Lord Lister, Sir Michael Foster, the present incumbent and Sir William Turner the president-elect for next year. Sir William Turner is best known abroad as an anatomist and anthropologist and for many years the guiding spirit of the great medical school of the University of Edinburgh. Here he is also intimately known to and beloved by the profession as President of the General Medical Council, the Executive Committee and Senate of the British Medical Association.

The war upon secret commissions in the medical profession is still raging in the columns of both the lay and medical press. The profession not unnaturally bitterly resents collusion with undertakers and consequent indifference to or even interest in the death of their patients being held up as a sample of what not only exists but may become dangerously prevalent if the "commission habit" be not checked. It is justly felt that such an accusation as this, based simply upon the allegations of one druggist and one optician, that physicians expected commissions from them, neither of the accusers daring to give their names, is hardly little short of monstrous from an ex-judge who is supposed by his position to have some knowledge of the laws of evidence. Sir Edwin Fry is out in another long letter to the *Times* in which he reiterates his former nameless depositions as adequate "evidence;" not, he now admits, for condemnation or even general accusation but for "inquiry." How anybody is to inquire into charges to which neither dates, names or particulars of any sort are attached he does not vouchsafe to say.

There is no question that Dr. Saundby's unfortunate statement that after investigating such charges as it could hear of the Medical Council found that in no case were commissions offered in advance as inducements to certain lines of action but "only as presents for favors conferred," leaving it to be implied, what he was very far from meaning, that the acceptance of "presents" was a comparatively trivial and venial affair, has made an unfavorable impression. And it also furnishes Sir Edwin Fry with the fresh ammunition of which he was sadly in need.

The extravagance of Sir Edwin's first insinuation that there was serious danger of doctors letting their patients die in order to secure heavy "presents" from undertakers, has defeated his own purpose and cast general discredit upon the whole crusade. The public takes but little interest in the matter and most of the letters in the newspaper are from medical men, most of them treating the insult with the silent contempt which it deserves, but frankly admitting that there are numerous little financial collusions as to drugs, mineral waters, wines and occasionally instruments and appliances, not in any way criminal, scarcely even immoral, but undignified and undesirable.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 4, 1899.

The President, William H. Thomson, M.D., in the Chair.

The first paper of the evening, entitled

ANEMIA AS OBSERVED IN GYNECOLOGICAL PRACTICE WITH SOME PRACTICAL SUGGESTIONS AS TO DIAGNOSIS AND TREATMENT

was read by Dr. W. Gill Wylie. He said, in brief: Anemia is always due either to blood loss or perversion of cystogenic tissue. Women are more liable to anemic conditions than men because their periodical blood losses in menstruation and childbearing keep their blood in a state of unstable equilibrium in which other causes easily affect it. Besides these natural reasons for the greater frequency of anemia in women there are others. Up to ten years of age boys and girls are brought up in practically the same way; but after this the girl gets much less of light, air, and exercise than the boy. Besides, she is, as a rule, compelled to work harder mentally and with less relief from strain during the years from twelve to eighteen than at any time in life. Just when she should have a surplus of energy to devote to the great developmental changes that are taking place in her physical organism she is employed almost continuously in the work of developing her mental faculties. Exercise is apt to be neglected, diet to be the result of caprice, while serious calls are being made by the physical and intellectual spheres.

This manner of life at an important formative period leaves the hematopoietic system weaker and less resistant and invites anemic conditions, as it also furnishes a basis on which develop various other functional and even organic troubles such as undeveloped uteri, chronic metritis, uterine fungosities, metrorrhagia, small and undeveloped cervices, which are especially liable to tears that later increase the liability to uterine subinvolution, besides a whole series of nervous troubles. In chlorotic conditions what might otherwise seem no more than ordinary menstruation may require curettement, and fungosities will often be found, for normal menstruation in chlorosis is really abnormal.

Particular anemic conditions are often due to some latent hemorrhagic lesion. Ulcer of the stomach runs a latent course with special frequency. Welch and other

pathologists have shown that gastric ulcers or healed remains of them are found very often post-mortem when the history of the patient shows no indication of the presence of an ulcer. In these cases a diet of milk for a few days, with careful watching of the stools, will enable one to decide whether there is any concealed hemorrhage or not. This gives us the most reliable means of deciding as to the presence of a duodenal ulcer which so often runs a latent course.

Anemia, however, may be the result of a chronic colitis, or of an appendicitis, without peritonitis. In a recent case on operation there proved to be a combination of a gall-stone and a patulous appendix, especially liable to irritation. There are are some very interesting cases of anemia connected with chronic appendical conditions, yet without perforation or purulent conditions. In nine such cases a prominent symptom always was nausea.

Gynecological conditions often cause anemia. The various forms of uterine hemorrhage produce it, and concealed hemorrhage may cause an insidious drain. Bleeding may take place into cysts, or into adhesions, or in old fibromata. Vascular growths may develop from old fibromata, cause intense anemia, and even the appearance of the cachexia of malignant disease. Even after examination they are sometimes thought to be cancer and declared to be inoperable. When operation is attempted, however, it is wonderful how well such patients stand large losses of blood during the operation. The blood-making organs have, as it were, grown accustomed to having serious calls made on their functions, and they are prepared to respond. Though anemic looking, before operation such patients react well even after a bloody operation. The anemic state should not be thought a contra-indication to operation. Plenty of liquid should be given during the days of preparation for the operation and subcutaneous injections of normal salt solution just after it will soon restore the circulatory equilibrium disturbed by blood losses. If liquid is allowed to be taken less than two hours before operation it may give rise to troublesome bleeding from small vessels that is very hard to control during the operation. Patients need not be denied the fluid they crave more than this, otherwise post-operative thirst will be excessive and prove a source of restlessness.

The second paper of the evening, entitled

THE PRESENT STATUS OF OUR KNOWLEDGE OF CHLOROSIS

was read by Dr. Thomas A. Southworth (see page 485).

Dr. Manges opened the discussion. He said that the opinions that attribute considerable weight in the etiology of chlorosis to gastro-intestinal disturbance are well founded. In chlorosis there is often present not only hyperacidity but hyperchlorhydria and there is also increased motility. Six or seven years ago Minot thought he had discovered the real reason for chlorosis in gastroptosis, downward displacement of the stomach, which by interference with the blood and nerve-supply to the spleen disturbed the hematopoietic functions. He found in nearly every case that the lower border of the stomach in chlorotic cases extended below the umbilicus, but, as Leo showed, Minot used large quantities of carbonic-acid gas in his demonstrations, and what he really proved was not a gastroptosis in every case, but a supradistensibility of the stomach.

There is no doubt, however, of the frequency of gastro-intestinal disturbances, but this should not keep us from seeing that our patients get enough to eat. In fact, it is always advisable to force the feeding. It can do no harm unless when the supposedly chlorotic condition is really a secondary anemia and due to a latent gastric ulcer with frequent hemorrhages therefrom. Such ulcers are much more frequent than is thought, but with careful and frequent examinations of the patient and her stools they will be surely detected.

Hoffman criticizes Jaccond and other French authorities for citing cases of supposed chlorosis with recurring fever sometimes as high as 103° F. It is probable that in these cases what was really present was a latent tuberculosis. Clifford Allbutt, in his "System of Medicine," in referring to the treatment of chlorosis paraphrases Osler's expression with regard to the use of quinin in malaria: that no case of chlorosis will fail to respond to iron properly administered. There are exceptions, however, to every rule, and certain cases of chlorosis are extremely obstinate even to long-continued iron treatment. It is in these cases that certain auxiliary methods of treatment are useful. Olliver has shown that during rest there is twenty-five per cent. more blood circulation through the muscles; hence, the value of rest in chlorosis when the oxygenation is limited by the lessened oxygen-carrying power of the blood.

Dr. Ewing said that the point of special interest brought out by Dr. Southworth's paper was that it is not easy to diagnose chlorosis from secondary anemia. There is an essential difference between the two inasmuch as in true chlorosis there is a disproportionate decrease of the hemoglobin of the blood, while in secondary anemia corpuscles and hemoglobin are reduced more or less equally.

As to the cause of chlorosis, its much more frequent occurrence in women shows that it is related to certain sexual factors. The practically constant presence of gastro-intestinal trouble shows that this has an etiologic relation to the affection. Further work along these lines will reveal the exact causal elements and so enable us to take chlorosis out of the list of primary or essential anemias.

Dr. Weber said that chlorosis in his experience is at least as common among the lower classes as the upper. When the condition cannot be cured after long and faithful treatment then it will usually be found not to be chlorosis. It will prove to be a secondary anemia or latent tuberculosis. We do not know the cause of chlorosis but we can cure it. The treatment with iron must not be continued merely for one month to six weeks, but must be kept up for three or four months without interruption. Blaud's pills are as good as any other form of iron provided they are not too old. If, when they are crushed (and it is in this way they should always be given), they are green within they are still active but if red

they are inert. When they cause gastric disturbance they should not be given on an empty stomach because of the caustic effect of the potash they contain. Dr. Wylie's suggestion as to the careful frequent examination of the stools in chronic anemia or chlorosis is very important as it will often disclose the reason why a case obstinantly refuses to react to treatment.

DR. SAVAGE said that the President of the Academy had gotten at the root of the matter in asking a gynecologist to open the discussion on chlorosis. The disease is practically always due to some gynecologic factor. An infantile uterus and the menstrual disorders connected with abnormally developed internal genital organs are usually at fault and often require active treatment.

DR. WYLIE, in closing the discussion, said that the hygienic conditions in the upper classes have changed greatly during the last twenty-five years, and that now we see less chlorosis among them than used to exist. He could not see how infantile uterus or undeveloped sexual organs can have anything to do with chlorosis, and as for treatment of such patients by the use of tampons, etc., he would think it justifiable only under very serious conditions As to sexual examinations of such subjects, he considers it scarcely justifiable except under ether.

DR. SOUTHWORTH said that of course he considers chlorosis distinct from secondary anemia though it is hard in certain cases to differentiate it. It is probable that chlorosis is due rather to the prevention of the formation of hemoglobin, and its consequent diminution because of its being used up in metabolic changes rather than to any active destruction of the iron compound going on in the system. Dr. Weber's expression, that the supposed cases of chlorosis that do not yield to treatment will be found not to be chlorosis, he welcomed most cordially. At times true chlorosis requires judicious persistent treatment and yields not quite as rapidly as is hoped, but the disease is, as a rule, very amenable to proper treatment.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Proceedings of the Twenty-fifth Annual Meeting, Held at Chicago, October 3, 4, 5, and 6, 1899.

THE Association met in Handel Hall, and was called to order by DR. HAROLD N. MOYER of Chicago, Chairman of the Committee of Arrangements. REV. H. W. THOMAS invoked divine blessing. Dr. Moyer introduced JUDGE CAVANAUGH of the Superior Court, who, in the absence of Mayor Harrison, delivered an eloquent address on behalf of the city and State. DR. FRANK BILLINGS of Chicago followed with an address of welcome on behalf of the profession of Chicago, after which the president, DR. DUNCAN EVE of Nashville took the chair. The report of the secretary, DR. HENRY E. TULEY of Louisville, was read. It stated among other things that but few deaths had occurred during the year. There are 300 members on the roll at present. Provision has been made for the issuance of a volume of *Transactions* this year. The treasurer's report by DR. DUDLEY S. REYNOLDS of Louisville was also read, which showed a balance in the treasury of $133.96. Both reports were accepted and referred for publication. The committee on credentials, DR. C. S. STANTON, chairman, reported 41 new members.

At this junction, the first vice-president, DR. A. J. OCHSNER of Chicago took the chair, and DR. EVE delivered his presidential address. He took for his subject

MALPRACTICE AND THE DAMAGE SUIT.

Strange as it may appear, he said, no systematic work gives a formal or technical definition of malpractice. He therefore had to quote from a well-known jurist on this subject: "Malpractice is the unskilful or negligent treatment of a patient by a physician or surgeon, or some one undertaking to act as such, resulting in injury to the patient." To constitute malpractice, unskilfulness and injury, or negligence and injury, to the patient must concur. The inquiry is natural, "What is meant by unskilfulness?" It is the want or absence of learning and experience in medical science. How much skill is required? The answer is "ordinary skill." What is ordinary skill? Such skill as is usually possessed by the profession at the time and place, when and where, the patient is treated.

Finally, the speaker urged in a forcible manner that the profession stand as a unit by the innocent victim when unjustly attacked, as if it were a matter of personal concern to each, remembering that when one member suffers the reflex action is felt by all.

SURGICAL SECTION.

DR. JACOB FRANK of Chicago read a paper on

VESICO-RECTAL ANASTOMOSIS.

Experiments have been conducted by him on the implantation of the ureters into the rectum, which justify the conclusion that in every instance there is an ascending infection of the ureters which terminates in the kidney. Since this is an established fact, as verified by both microscopic and macroscopic study of dogs, he has every reason to believe that no better result could be attained in the human being, and from this circumstance alone the implantation of one or both ureters can never become popular. Various operators have devised different methods for the relief of exstrophy of the bladder, but Maydl's is the safest and best because, according to his technic, the ureteral openings are not anatomically interfered with, hence there is a fortification against ascending infection.

The operation consists of anastomosing the bladder to the rectum with the author's decalcified-bone coupler. The technic is as follows: In a male dog the incision is made in the groin, and in a bitch in the median line. Generally, the bladder is found distended, and is emptied by squeezing it gently with the hand, when the urine escapes through the natural channel. The rectum is next picked up and freed of its contents, as in any intestinal operation. The bladder and rectum are then brought forward and placed in position for anastomosis. Two or three interrupted Lembert sutures are now taken about half an inch below the lower ends of the incisions de-

termined upon in the bladder and rectum, care being exercised in selecting them that the coupler, when it is inserted, will not encroach upon the ureteral openings. A longitudinal incision is then made in the bladder large enough for the coupler selected, and a puckering-string applied over and over the cut margin. The rectum is next opened in its long axis, and a puckering-string similarly applied. The suture should be inserted so that the free ends lie uppermost, thus facilitating easy tying. The operator now slips the coupler into the bladder opening, at the same time gently spreading the collars apart, while an assistant makes one knot and draws down on the puckering-string until the rubber tubing is felt; another knot is made and the ligature cut off short. The other half of the coupler is then slipped into the rectal opening and likewise tied and cut off. Several interrupted Lembert sutures are inserted around the borders to make the work more secure. The operation is simple, and can be accomplished in ten or fifteen minutes.

The speaker said that he has not had an opportunity of trying this new method on the human being yet, although it was tried on the cadaver. Of the 15 dogs operated upon, 10 recovered and 5 died. In the first two experiments the technic was imperfect, and a great deal of unnecessary work was done, which undoubtedly contributed largely to the failures. As a rule, the dogs are quite sick for the first few days, and show signs of pain, with rise of temperature. For a week after the operation urine and feces are voided oftener than after this period. Dogs raise the leg as though in the act of urinating, without accomplishing anything, and finally squat down and micturate from the rectum. The animals that have been kept accustom themselves to their condition and urinate periodically. The feces are passed in a liquid form, being softened by the urine. Two of the dogs which were operated on about six months ago are alive and in good health.

Dr. H. O. Walker of Detroit commended the paper for its originality. His experience with ureteral implantation has been limited, but having read the literature on the subject, he was impressed with the practicability of the operation described by the essayist, believing that it will do away with the implantation of the ureter into the rectum.

Dr. Thomas Charles Martin of Cleveland said the essayist was less enthusiastic than he was justified in being, for in a human subject who has exstrophy of the bladder this new operation could be performed without opening the peritoneal cavity.

Dr. John L. Jelks of Memphis, Tenn., then read a paper on

SOME COMPLICATIONS MET WITH BEFORE AND AFTER OPERATIONS FOR HEMORRHOIDS, THEIR CAUSES, PREVENTION, AND TREATMENT.

He reported several instructive cases. He said a surgeon sometimes in dealing with a simple rectal trouble encounters serious disease of the uterus and and its adnexæ. Without the entire relief of both or all conditions the patient will probably feel that little benefit had been given her. Syphilis and gonorrhea may be and often are causes of rectal troubles. When a patient with hemorrhoids has gonorrheal infection the latter becomes a serious complication.

Dr. Joseph M. Mathews of Louisville said that no intelligent surgeon to day uses carbolic acid for the treatment of internal hemorroids. In operating the clamp and cautery or the ligature may be used. The former method of operating is not so liable to be followed by the complications referred to by the essayist. Personally, he would operate on hemorrhoids regardless of complications, such as pregnancy, a displaced uterus, etc.

Dr. George F. Keiper of Lafayette, Ind., then read a paper on

THE MASTOID OPERATION

and reported several cases. He directed attention to the possible injury to the facial nerve in operative work either upon the mastoid or the middle ear. He believes that surgeons have been reckless in this regard and the patients have suffered in consequence. If the facial nerve be wounded or cut through all authorities are agreed that it cannot be regenerated in less time than from twelve months to two years, if at all. Hence the importance of taking due notice of its presence in operative work.

Dr. Gustavus M. Blech of Chicago contributed a paper on

MODERN SURGICAL TREATMENT OF HEMORRHOIDS.

Since a hemorrhoidal tumor is but the result of an inflammatory process, he believes that germ infection must be the main etiologic factor. A *locus minoris resistentiæ* is produced by certain mechanical influences which, however, in the light of modern pathology can be considered only as predisposing causes. In this class belong straining during defecation, obstruction of the portal vessels from liver disease and abdominal tumors, pressure produced by the gravid uterus, pressure on the veins from impacted feces, etc. That germs are primary factors in the production of hemorrhoids the author is satisfied from observations in his practice.

As to the treatment, he said that in the earlier years of his professional career he was in the habit of removing internal and external hemorrhoids with the ecraseur. His objection at present to this method is that the wire of the instrument is very apt to break, leaving the operator in a dilemma, especially when the operation is half completed. Secondly, the cut surface is not accurate, nor can it be regulated. No matter how close the wires are kept down to the base of the pile the ecraseur cuts as it pleases, and not as the surgeon desires it. Thirdly, it frequently happens that after the operation is finished complete separation of the tissues does not take place, and if the screw is tightened some tissue is drawn into the stem, and if continued, the stem is apt to bore itself into the rectal wall. He does not favor the Whitehead operation. His method of operating for internal hemorrhoids differs but little from that of most surgeons. If he has to remove but one tumor of large size he simply throws around its base a temporary ligature, cuts off the entire tumor, and then sews the wound with interrupted sutures in the direction of the axis of the rectum.

BETA-EUCAIN AS AN ANESTHETIC IN EYE, NOSE, AND THROAT WORK.

DR. WILLIAM H. POOLE of Detroit read this paper, which will appear in next week's issue of the MEDICAL NEWS.

INTOLERANT ULCERATION OF THE RECTUM.

This paper was read by DR. STERLING B. TAYLOR of Columbus, Ohio. He reviewed the surgical anatomy of the anal portion of the rectum at considerable length. In the early stages of intolerant ulceration physicians are inclined to discredit the presence of any severe pain, inasmuch as in its incipiency it is merely a rent or tear in the mucous membrane. This is prevented from healing by the lodgment of small particles of fecal matter, which produce irritation and inflammation, and eventually painful ulceration. The extreme pain makes its appearance with the unhealthy granulations. Pain is not the only disagreeable accompaniment, as there is often annoying and sometimes dangerous hemorrhage, especially if the ulcer be located high. The usual seat of the ulcer is at the posterior commissure, and it is here that it is most painful. The anterior commissure is the next favorite seat of the ulcer.

As regards treatment he recommended the method practised by Martin, which he considers simple and effective. General anesthesia is not required, but simply infiltration anesthesia, which is practised by the injection of a few drops of a $\frac{1}{10}$ of 1 per cent. solution of eucain or cocain around the ulcer. A slight incision is then made through the membrane and integument down to, but not through, the sphincter. He then packs with a small piece of iodoform gauze. The bowels should be kept open with some laxative, preferably a mineral water. Apenta water is both pleasant and efficacious. Several cases were reported in which the Martin method of treatment was resorted to. The essayist held that rectal ulcers can be excised under eucain anesthesia without pain.

The address in medicine was delivered by DR. J. A. WITHERSPOON of Nashville, Tenn. He selected for his subject

TYPHOID FEVER.

In this day of progressive medicine, when the whole profession is anxious to elucidate the etiology of disease and its prevention, no field has been so thoroughly gone over, and in none have the trials or hardships been so difficult as in the study of the plain, old-fashioned disease —typhoid fever. While the laboratories with their facilities for studying pathogenic micro-organisms have made wonderful progress, the speaker said that he belongs to that school which believes that while the diagnosis should be made with the assistance of the bacteriologist, more importance should be attached to making it clinically at the bedside. In other words, he is absolutely opposed to doing away with the good, old-fashioned methods of examining the patient and relegating the system of our forefathers to the rear, and making diagnoses purely in the laboratory. Typhoid fever is a specific toxemia, it being produced by the typhotoxins elaborated in the system from the bacillus of Eberth. The speaker then dwelt at length on the differential diagnosis of typhoid fever and what he calls "toxo-enteric fever."

In speaking of the treatment of these diseases he stated that the man has never lived who could formulate prescription number one and formula number two, etc., have them made in Detroit or any other city, and tell him how to treat a case of typhoid fever in the active stage of the disease. He is unalterably opposed to any man putting up prescriptions of this type for him.

OBSTRUCTIVE GROWTHS OF THE PYLORUS.

This was the title of a paper by DR. J. E. ALLABEN of Rockford, Ill. The author reported a successful and interesting case of pylorectomy, after which he drew the following deductions:

1. Cancer is one of the most potent factors in the causation of death, with a tendency to constantly increase in frequency of occurrence.

2. Gastric cancer occurs in about one-fifth of all primary cases.

3. In gastric cancer the pyloric region is affected in sixty per cent. of the cases.

4. The treatment of gastric cancer directed toward a permanent cure is, in the present state of our knowledge, limited wholly to surgical methods.

5. As early total extirpation of malignant growths with the hope of permanent cure is the goal toward which we are constantly striving, and as these growths in gastric cancer occur at the pyloric region in sixty per cent. of the cases, it would seem to follow as a natural conclusion that pylorectomy would be the treatment most frequently prescribed for the cure of this malady.

6. Inasmuch as early diagnosis is the greatest requisite for directing proper radical treatment, the internalist and the surgeon should turn their best efforts in this direction.

7. If the operation of pylorectomy were performed before obstructive symptoms manifest themselves, and before the occurrence of metastasis, the immediate results would be as favorable as in any other abdominal work, and the remote results as good as in extirpation of carcinoma of the breast.

DR. J. L. BOOGHER of St. Louis, Mo., then read a paper, in which he dwelt principally upon the value of prostatic examination in the treatment of associated affections.

WHAT BECOMES OF THE MEDICINALLY TREATED CASES OF APPENDICITIS?

This paper was read by DR. LEWIS SCHOOLER of Des Moines, Iowa. The author predicts that the facts, as disclosed by greater observation and the increasing experience of medical practitioners, will inevitably show that the present position occupied by them is untenable. Patients who are treated by means of medicine only either die under such treatment or later are cured by operation. To the above there should be noted a single exception, namely, those cases in which cure is spontaneous. This occurs by rupture into the bowel, vagina, bladder, or externally. Instances of this method of cure are familiar to all. It is singular, therefore, that in view of

such familiar occurrences medical men do not take the hint that Nature is so persistently urging upon them and comprehend more clearly the fact that removal of the offending cause is the only rational procedure. It is the only one that is approved by Nature, pathology, observation, and science.

Dr. H. C. Wyman of Detroit, Mich., followed with a paper in which he dwelt on the surgical features of appendicitis.

INTESTINAL OBSTRUCTION FROM BILIARY CALCULI.

Dr. J. Wesley Bovée of Washington, D. C., read a paper with this title. He stated that intestinal obstruction from biliary calculi is not very common. Brinton found in 500 cases of intestinal obstruction but 24 cases due to gall-stones, and Leichtenstern found but 41 in 1544 cases of bowel occlusion. In the Manchester Royal Infirmary but 1 case in 50,000 patients treated for all troubles was found. As it is a condition practically limited to late life its rarity is to be expected. The author then dwelt upon the varieties of obstruction, the location, causes, symptoms, and prognosis.

In considering the treatment he stated that Hippocrates and later others recommended the injection of air into the bowel. Tobacco smoke and infusion and different gases have been thus employed. Purgatives are positively harmful. Morphin and belladonna are the two best drugs in this condition. Of course the use of electricity has not been omitted. With medical treatment nearly half the patients recover, but is that a sufficiently large proportion? In 1662 Barbette recommended laparotomy for acute intestinal obstruction, and as abdominal surgery is now practised its use in acute obstruction of the bowel from biliary calculi should give brilliant results. Medicinal treatment may be employed for a short time, and, failing, should be superseded by laparotomy, with a careful exploration of the abdominal and pelvic contents. The seat of obstruction being found, the condition of the patient and the degree of mobility of the stone in the bowel will guide the operator in the subsequent steps. The plan of Tait, of passing a strong needle obliquely through the bowel wall into the stone to break it up, may first be tried, the puncture wound being closed by a Lembert stitch. This failing, the stone should if possible be pushed higher in the bowel and a longitudinal enterotomy performed with extraction of the stone. Gangrenous bowel, perforation, or localized peritonitis, with or without pus, should be treated *secundum artem*. It is always well to look for a second obstruction, as this has caused death in some cases. The deaths following laparotomy for this condition are nearly always from shock or sepsis, a strong argument for early operation. It would not seem improbable that early laparotomy in these cases should have a mortality of less than 10 per cent.

The address in surgery was delivered by Dr. Lewis S. McMurtry of Louisville, Ky. He selected for his subject

THE ESSENTIAL REQUIREMENTS OF A MODERN OPERATIVE PROCEDURE.

During the past fifteen years the province of surgery and its scope have been greatly enlarged. Many diseases and injuries that were formerly treated on the expectant plan and by palliative measures, with little hope of permanent relief or cure, are now cured by judicious surgical intervention. Notwithstanding the increase in hospital facilities in cities and towns many important surgical cases must receive immediate attention at the hands of the family physician from the very nature and urgency of the disease or accident. Such cases are classified as emergencies, and they include many major as well as minor injuries. When a major or minor surgical operation is to be performed certain fundamental principles of asepsis should be observed, and yet it is comparatively exceptional in private homes for minor surgical procedures to be carried out without the presence of pus following the operation.

The speaker said that there are three important steps to be observed: The first is the administration of the anesthetic. This requires skill, which can only be acquired by practice; hence, medical students should receive practical instruction in the administration of anesthetics. The second element of a surgical procedure consists in the control of hemorrhage. In the early days of abdominal surgery it was common to disregard the question of hemorrhage. All those present would remember the days when the drainage-tube was more frequently used than it is now, and that within forty-eight hours after an operation it was customary to pump out considerable quantities of blood as the result of oozing from small vessels that were ignored during the operation. Nowadays, when more attention is given to hemostasis, hemorrhage is lessened on account of attention being directed to the small vessels. A third indication, and one to which the speaker devoted the remainder of his remarks, was the important one of asepsis.

Dr. John D. Kyle of Indianapolis then read a paper in which he discussed the treatment of nasal stenosis due to deflections of the nasal septum, with or without thickening of the convex side. In his opinion the most frequent cause of deflection is trauma. Ulceration of the septum or inflammation within it, as noted in a child suffering with congenital syphilis, and hypertrophy of the turbinates are causative factors. A strumous or uric-acid diathesis may predispose to perichondritis and subsequent deflection.

Dr. Emory Lanphear of St. Louis, Mo., contributed a paper in which he dwelt on the removal of the cervical sympathetic for epilepsy, exophthalmic goiter, and glaucoma. He mentioned the work of Jonnesco and other surgeons along this line saying that this field of surgery is worthy of further study and investigation.

SURGERY OF THE TURBINATED BONES.

The author of this paper was Dr. J. A. Stucky of Lexington, Ky. He did not discuss operative procedures on the turbinated bodies, nor on any of the soft tissues covering the bone, but rather the bone itself. While it is true that the tissues covering the bone are far more frequently found in a pathological condition, and require surgical treatment, it is also true that the bone itself in many in-

stances is at fault. When this is the case the mucous membrane and turbinated bodies may be entirely obliterated by chemical and electric cautery, or scissors, forceps and snare, and the latter condition of the patient be worse than the former, because of the remaining cicatricial tissue and unnatural dryness of the parts. He then called attention to what he considers the best method of removing a part or whole of the bone. The first and most important desideratum in all intranasal operations is to remove only just as much tissue as is absolutely necessary. The crushing or punch forceps, spoke-shave, and snare should only be used inexceptional cases. In removing a part or whole of the middle turbinate, correctly shaped scissors is the only instrument needed. For this purpose he has found none equal to those devised by Dr. C. R. Holmes of Cincinnati, one for each turbinate, right and left. For turbinectomy or turbinotomy of the lower bone, the narrow-bladed scalpel, saw and long straight scissors are needed. An incision through the soft tissues is made along the edge of the bone; this is peeled back with the back of a scalpel and the bone exposed. Should this be too firm to cut with the scissors, a narrow, thin saw is used. In cases where the knife, saw, and scissors cannot be used to complete the operation on account of the size, depth, and conformation of the nasal chambers, the snare is used to complete the removal of the posterior portion. Little or no dressing is needed after the operation, except when the lower turbinate has been entirely removed; then strips of gauze placed smoothly over the wound are allowed to remain twenty-four or thirty-six hours, then carefully removed, after thoroughly softening with fifty per cent. hydrogen dioxid. The subsequent treatment consists of keeping the parts clean until union is complete.

MAMMOTH OVARIAN TUMORS: REPORT OF A CYST WEIGHING 245 POUNDS.

This was the title of a paper read by DR. JAMES B. BULLITT of Louisville. Only growths weighing 100 pounds or more were considered as mammoth tumors. A search through literature has developed reports of twenty-three such cases. Brief summaries of these cases were presented. The largest of these tumors weighed 202 pounds. The speaker added a twenty-fourth case by reporting in detail a case in which operation was performed by Dr. A. M. Cartledge of Louisville in May, 1897, the tumor-sac and contents together weighing 245 pounds. A great many adhesions were encountered, and the operation was prolonged. The woman rallied from the shock and was in good condition at the end of five days, when obstruction of the bowel occurred and she died on the seventh day.

OBSTIPATION AND ITS RADICAL TREATMENT.

DR. THOMAS CHARLES MARTIN of Cleveland, Ohio, read a paper with this title. He said that the rectal valve is an individual anatomic organ in itself, and must now be reckoned with in studying the operations of the integral mechanism of defecation.

When the muscular elements are relaxed and the gut is either greatly dilated or else is even in lesser measure distended, the valve is passively supported by its fibrous band across the channel to resist the hurried or uncontrolled descent of the feces. The presence of the band of fibrous tissue under the free margin of the valve provides a *control* to receive or retain a bolus, or, it may be said, the several valves receive a series of boluses till a sufficient pressure is made to stimulate the complex involuntary mechanism of defecation to further propulsion of the feces, or to a reversed peristalsis. The presence of the feces or the involuntary movements incident to their presence, signals the consciousness to cooperative voluntary expulsory effort, or gives warning of the necessity of voluntary resistance. The valvular arrangement of the rectum provides for the minimum expenditure of energy on the part of the voluntary forces for the reason that the gut's contents are collected on the surface of the unyielding sacrum and steadied there to receive the pressure of the really expulsory voluntary effort. Such an arrangement of the feces further facilitates defecation for the reason that the entire contents of the rectum are not rushed upon the anus at once. If it be the function of the normal rectal valve to beneficiently retard the descent of the feces, it is obviously true that it may be the especial property of the valve, in certain other normal conditions to maliciously obstruct the descent of the feces. The patient is the subject of more or less chronic irregularity of defecation. On some days he makes frequent, partially successful attempts to evacuate the rectum, but may experience an unrequited desire for stool. He acquires the reprehensible physic habit. In time the periods of obstipation are interrupted by diarrhea. There is commonly an ineffectual straining at stool except in the case of fluid feces.

SURGICAL TOLERANCE AND RESULTS.

This paper was read by DR. F. F. BRYAN of Georgetown, Ky. He concludes that tolerance is due (1) to individuality of the subject; (2) to the vital resistance furnished by organs capable of performing their function; (3) by the immediate necessity for the part by the body as a whole, for the aid of the part operated upon, in carrying on life; (4) preventing or limiting shock; (5) limiting hemorrhage; (6) preventing and limiting sepsis and removing the same. Results will depend on (*a*) refusing operation to a hopeless class of patients; (*b*) painstaking care to make the procedure thorough; (*c*) demanding sufficient time for thorough convalescence and adaptation of the patient to the changes that have been wrought.

The following officers were elected for the ensuing year: President, Harold N. Moyer, Chicago; vice-presidents, A. H. Cordier, Kansas City, Mo., and S. P. Collins, Hot Springs, Ark.; secretary, Henry E. Tuley, Louisville, Ky.; treasurer, Dudley S. Reynolds, Louisville, Ky. Place of next meeting, Asheville, North Carolina; time, October 4, 1900.

Another Case of Fractured Spine at Roosevelt Hospital.— A man presenting similar conditions to those of Mr. Duryea has been brought into the hospital. He awaits operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, OCTOBER 21, 1899. NO. 17.

ORIGINAL ARTICLES.

THE ARID REGION OF THE UNITED STATES FOR PULMONARY TUBERCULOSIS.

BY J. O. COBB, M.D.,
OF FORT STANTON, NEW MEXICO;
PASSED-ASSISTANT SURGEON, UNITED STATES MARINE HOSPITAL SERVICE.

I TAKE an opportunity in this paper to answer the great many inquiries that have come to me from physicians and others by giving information through the MEDICAL NEWS direct to physicians relative to this section as a climate for their consumptive patients. As I have no local interest I can probably speak without coloring my statements with Western prejudices.

What actual knowledge I possess of the arid region has been gained by a residence here this summer, last spring, and last winter, during which latter season I was sent through Arizona and New Mexico to inspect Government reservations for the purpose of recommending the selection of a site for a sanatorium for consumptive patients of the Marine Hospital Service. In this connection I wish to call attention to some of the points of interest which impressed me while on this trip, and which may be useful to the physician in sending his consumptive patients out here for the climatic cure of the disease.

First and last, I am firmly convinced that any part of Arizona, Colorado, New Mexico, Mexico, or Western Texas above 2000 feet elevation is as good as another part for the acute case without complications, other things, of course, being equal, such as proper food, etc. I know that a large percentage of such patients sent here rapidly and permanently recover. Let me emphasize that for men in the acute stage one place is as good as another in the sections named so far as altitude is concerned. If the patient has friends, or if it is known that he can obtain all the necessary care at any particular place in the sections above named, let him be sent there. For women, those in an advanced stage and those with a tendency to hemorrhage, care must be exercised to select a site at a medium altitude; patients with stenosis must never go to a high altitude

I believe that for the average patient the climate of El Paso is as good as that of Colorado Springs; Albuquerque as good as Fort Stanton; Tucson and Phœnix as good as Prescott; Chihauhua and Aguas-Calientes as good as the City of Mexico. These places represent the average of each section, and if the physician has a patient in either, and he has all the other absolutely necessary requisites for his comfort, care, proper food, and peace of mind, then one need not worry, for all will have been done that can be done. I have met numbers of patients out here who have tried each place, and, of course, wherever one began to improve that was the place of all others. It is surprising what a vast fund of knowledge relative to climate, rainfall, altitude, and a thousand other unnecessary things these poor unfortunates pick up. I recall a case in Phœnix which I found to be fairly typical of the consumptive sent out to this country. This man, who was just ahead of me at the ticket office, interested me by calling for a ticket to Chicago, and seeing that he was very sick with tuberculosis I naturally made an opportunity to speak to him and inquire why he was returning to Chicago. He explained that thirty-three days before he had landed at Albuquerque, and as he could not notice any difference after a week's stay there, and being told that it was too high, he went on to El Paso, and from there still lower to Tucson. As I was much impressed with that beautiful little city, I asked him why he left Tucson. "Oh," he said, "it was too dry, and they have such awful dust storms." I asked him how many storms they had while he was there, and he said only one, but he knew he should die if he had to live through another. So he had come to Phœnix, and was leaving there because the place was ruined by too much irrigation of the alfalfa fields, and was, therefore, too wet.

Who was responsible for sending this poor, foolish man out here without sensible instructions to aid him to bear up against all the natural drawbacks to be found in a newly settled country? If one expects the climate to do all he will be wofully deceived. If the cases are diagnosticated early and the patient sent here promptly, I believe at least eighty per cent. will recover with out-door life, good food, and attention. Of course many patients will recover with only climate as an aid in spite of all hardships. Truly, though, I have been unable to find many of these.

Do not fail to impress upon your patient that he is to come out here to make it a business to get well. He must understand that the towns are small,

nearly all the hotels poor, and the boarding-houses even worse. There is very little beautiful scenery outside of Colorado. There is much that is dry, brown, dusty, and some that can be called grand though somber. The barrenness of the arid region in Arizona and New Mexico is appalling to the newcomer. The monotony of the ever-present sunshine, the dust, and the high winds make the sick and the well long for a drop of rain; and then add to this poor food and unsatisfactory accommodations, and it requires some courage on the part of the patient to remain here. Then let it be understood that coming here is a serious business, and that the stories of hunting and fishing (the latter especially) and other sports are exaggerated, and generally entirely untrue. Then, too, in all arid regions of the world dust and winds prevail, and I can see no reason to deny that there is a great deal of dust and high winds all over the sections under discussion. Let it be understood that there are many unpleasant features, and the disappointment will not be so great.

The consumptive must not come here believing that it is warm just because there is so much sunshine. At Las Cruces last January it was a little too warm at mid-day for long walks, while in the evening one required a heavy overcoat, and at night heavy blankets. There is a very marked difference between the midday and midnight temperature, and it is absolutely necessary to come prepared for cold weather, and flannels will have to be worn all the time.

I have noticed one thing out here which is very disgusting, and that is that the pillows and bedding have the odor of perspiration so peculiar to the consumptive. Every health-seeker should buy pillows and blankets and carry them wherever he goes if he desires comfort and cleanliness. Every place seems to have the abominable cotton padded "comfortables," which cannot be and never are washed. In a large hotel I found that I had to spend a night under one of these foul things, and I noticed next morning that it had several large spots of dried sputum on it. If one wishes to feel comfortable and be free from disgusting odors let him carry his own pillows and blankets. Besides, if one always has the same covering there is not so much danger of catching cold.

Never believe that the room offered to you has been properly disinfected; also, never believe that a consumptive has not preceded you. I call attention to this for I believe that many persons with mild cases become reinfected here by occupying rooms which were formerly in possession of persons ill in the last stages, and I have heard of a few individuals who had come out with relatives and later contracted the disease, probably by occupying infected rooms.

Physicians should especially direct their patients in the management of the sputum. I never dreamed that man was such a filthy animal until I visited Tucson, El Paso, and the other places where consumptives go by hundreds. I never saw anything more disgusting than the walks in the plaza at El Paso. The efficient president of the Board of Health of that city has made many enemies and brought a great deal of abuse and ridicule upon himself by fighting this dangerous nuisance, and at last he has succeeded in having a law passed forbidding spitting in the streets. I believe he has sufficient temerity to enforce the law. At any rate, it is our duty to aid him by careful instructions to our patients. The patients should be taught not to cough in public places, and to use the sanitary sputum-cup or pocket-bottle.

There has grown up in the Western country a spirit of exaggeration in respect to each locality that, to say the least, borders on the untruthful. Each place has all the virtues, while its nearest neighbor is nothing but a death trap. The expression is often heard that no consumptive was ever known to get well there. Even the doctors join in such silly expressions, and often display a spirit that I am sure is engendered by their own local interest. I am sorry to say this, but I believe it to be true. Especially is this true of their actions toward places of different altitudes from their own. Then, too, wherever one goes every citizen can tell you the average rainfall of his section for years, and he is ever ready to direct your attention to the statistics of other localities that are wetter, but never to those that are dryer, for his desire to furnish you with necessary information never reaches that far.

The places mostly frequented range between 2000 and 7000 feet in altitude, and some are as high as 8000 feet. The greater the altitude the greater the rainfall, and consequently the less dust and more luxurious vegetation; the lower the altitude the greater the barrenness and prevalence of dust storms. Don't let your patients worry about the rainfall, for there is practically none in winter anyway, and in summer what falls is in down-pours which runs away or is rapidly absorbed. The country would be much better if there were more rain.

I want to impress upon physicians the importance of mapping out to their patients the different discouraging problems which they are sure to encounter. I have taken every opportunity to talk with the doctors and consumptives out here for the purpose of ascertaining their trials and hardships.

In a few instances I have found patients who were here under full and intelligent instructions, and who were ready to laugh at the bad food and discomforts, and were making it a business to get well. It does one good to meet with some patients sent out by doctors with sensible directions, even though in nearly every case these doctors have never been here. These are the patients, too, that are doing so well, and in each the diagnosis had been made early.

There has grown up an absurd idea that individuals with destructive valvular lesions cannot live in any altitude above 2000 feet. A little thought will convince one that the average lesion case without stenosis will do even better here than at the level of the sea, especially if compensation has taken place. I have failed to examine one consumptive here who has not referred to his heart and asked if I thought it would stand the altitude. I have examined a few patients who had been directed to leave the high altitude and go lower "on account of their hearts." There was nothing the matter with their hearts except in two instances, and these had irritable hearts from too liberal use of tobacco and coffee. Even the well person cannot smoke and drink tea and coffee with impunity without a feeling of fulness and distress in his chest. This is especially marked at an altitude of 5000 or 6000 feet. I believe much of the dizziness and fulness of the head at high altitudes is due to the use of coffee, tea, or tobacco.

Pulmonary hemorrhage is a question about which I am unable to offer any positive opinion, but one which I have investigated carefully. Physicians residing in the greater altitudes deny that their patients are any more likely to have hemorrhage than at a much lower level. I cannot very well believe that, for the reason that the higher one goes the greater is the relative action of the heart. That is plain, for as we take off the air-pressure we are lowering the "governor," and the heart's action is accelerated and will "race," for there being less air pressure there is necessarily greater relative pressure from the arterial tension. It seems, then, that if the wall of a blood-vessel were already weakened there would be danger for the consumptive to go at once to a high altitude; therefore, if the patient has shown a tendency to bleed and there is a cavity present, I would suggest that he be started in at a medium altitude and gradually ascend.

Tubercular pneumonias involving small portions of the lung are quite common, I am told, and I believe are more often noticed in high altitudes than in lower ones. The newly infected area softens rapidly and a cavity forms at that point.

Consumptives with large cavities rarely recover if they have high temperatures and the cavity is infected with the steptococcus. It is admitted by all that these patients seldom if ever recover in an altitude above 5000 feet. One of our large sanatoriums here refuses to accept such patients, but it is the unexpected that often happens in such cases. I know a woman with a cavity as large as an orange, and one can hear the gurgling in this cavity two feet away, and yet she has gradually improved, and I think will recover. She has been here three years in an altitude of 3800 feet. I also know a man with a cavity the size of a lemon, stuck up against the anterior wall of the thorax like a swallow's nest. He has no other trouble, but still expectorates bacilli from this cavity. His case dates from 1867. Most of his time has been spent in El Paso, but he has also lived in Colorado at a greater altitude. I merely mention these cases to show that some of the patients so afflicted do get well, though they are few.

The physician in the East must be very careful in sending women here. Women often have irregular and scanty menstruation as the first symptom of the disease. Almost surely if they are sent to altitudes above 3500 feet they begin to menstruate freely and often dangerously. There are few women who are not troubled in this way when they first come here. I have heard of some who began to menstruate regularly after going to a high place. I think, however, that this was due to the general improvement of their health. I knew one young girl who usually had a hemorrhage from the lungs at the menstrual period, though she had no sign of uterine flow. She had a large cavity, and has nearly recovered.

Nearly all women are very nervous during the first few months of their residence here. They are highly apprehensive of impending danger, especially during high winds and dust-storms, and one expressed her feelings very clearly by saying that she had an almost overwhelming apprehension of the heart. Men have this feeling also, but not to such an extent. I am in absolutely perfect health, yet even now if I drink strong coffee or tea I have a very disagreeable sensation in my chest. It is nothing more than the heart going too fast for aeration of the blood. This can be stopped in half an hour by walking for that time and then lying down.

Women also have dyspepsias worse than men, and they do not sleep so well. With them, also, constipation is hard to control. High winds cause the air to become electric, and then one is stimulated and is buoyant. The dry air seems to drive away the blues even of the sourest patient. I notice that the consumptive here is more hopeful and happy than in the East.

If the diagnosis is made early, before complications have taken place, I believe that eighty per cent. at least of the patients sent here in that stage will recover. A great many who appear hopelessly sick at the East will also recover or the disease will be arrested. In spite of the dust people with laryngitis improve wonderfully in a short time. While at Las Cruces last December I played ball with two young men, one of whom had been brought to that place on a stretcher fourteen months before. While at college he had eleven hemorrhages, when he contracted the disease. He promised to allow me to examine him, but I had to leave and never saw him again. He said that so far as he could tell he was perfectly well. The other case was one of twelve months' standing, and the man thought himself well, though I easily found the infected area in both apices. Near Fort Stanton is a young man following a flock of sheep. He herds them night and day, sleeping on the ground. To see him now no one would believe that a few months ago he could scarcely walk, and that only will power kept him alive. Another patient came in June and camped near the Reservation. He had a large cavity and mixed infection. He could not walk. Now he has very little fever, and rides and walks a great deal. It remains to be seen if this patient with mixed infection will eventually recover at an altitude of 6126 feet. These are only examples of nearly one hundred cases that I have seen incidentally, and some patients who have been here a number of years show no signs of the disease, and I have to take their histories for the correctness of the diagnosis. One can hardly believe that they were tuberculous and had recovered.

In the case of extensive dry pleuritic adhesions of both lungs, as a complication, I am told the patients invariably die when at an altitude above 2000 feet. All women should start in at an altitude of about 3500 feet, and ascend if they have no complications. Patients with a tendency to hemorrhage should not go to high altitudes. Persons with valvular lesions as a complication should be started in at a low altitude because very little exertion will set the heart racing and badly frighten them in spite of the explanation that there is no danger. Persons with stenosis should never be sent above sea-level. Physicians are advised to keep their bed ridden patients at home to die in peace. This country is bad enough to live in, and it certainly is hard to die here. It should not be forgotten that the trip is hard for a well person; for the sick it is a hardship. Individuals with one side badly affected and large cavities should submit to the Murphy operation before being sent out. If such are sent to places as low as Phœnix and Tucson there is a good chance for them to recover. If the patient has big cavities on both sides he must not go above the level of San Antonio, Tucson, or Phœnix, and even at these places the chances are against him.

Colorado is so well known I shall not attempt to name any place in that State. Arizona, New Mexico, and Western Texas are the parts of the arid region that I think are most desirable. As I said before, one place is as good as another in this region as far as the climate itself is concerned. For those in the acute stage the climate alone will cure most of them, and therefore it makes very little difference where they go. For those in whom the disease has advanced sufficiently to give rise to high fevers and dyspepsia, and who are easily chilled by the least exposure to cold it is necessary that the very best cooked food and attention be given. It is this class of patients which has aroused my solicitude especially. I have seen a number of them die and know that a great many die that should have been saved. A large percentage of these unfortunates obtain the glaring advertisements of some place with a Spanish or Indian name and are induced to try its extolled virtues. Their disappointment is woful. The food and lack of attention would make the well sick. Patients should be kept from the small Western town and from the ranch There is not one ranch in five hundred where one can obtain a palatable meal. With thousands of ranch cows about one rarely sees milk or butter at one of these places.

This arid region, which includes a large section of Mexico, has been pushed up, as it were, from 2000 to 8000 feet above sea-level. The climate has been changed and modified to such an extent that it is entirely different from that which one would notice merely by going up a high mountain. With a temperature of more than 90° F. in the shade one does not perceptibly perspire. The air is full of electricity. If I had the choice I should prefer to have consumptive patients here in summer rather than in winter. I believe it a great mistake to send patients here in winter and allow them to return East to spend a miserably hot summer, losing all they have gained. The consumptive will flourish in dry cold and succumb to moist heat. I have yet to see more delightful weather than that of last spring and summer, during which time I was at El Pasco, in the Tularosa Valley, and here at Stanton in the Sierra Blanca region. In the Rio Grande and Tularosa valleys the sun is blazing hot, and yet there is nearly always a breeze and one can find comfort in the shade.

Here at Stanton the spring, summer, and so much of the fall as has passed have been absolutely perfect. No one could find anything to add to it. The

record for more than twenty years shows mild winters with high winds in February, March and April.

Let me again advise against sending patients to small towns. El Paso, Phœnix, Albuquerque and Tucson are bad enough. Even in these towns with few exceptions there are no first-class, up-to-date hotels. In El Paso with its enormous transient travel and its large amount of business there is only one medium class house worthy the name of hotel; and there is not one good restaurant. Albuquerque has recently lost its fine hotel by fire, and now there is no place for the wealthy consumptive to go to in that city, for no one would tolerate the hotel accommodations there if he could help it. Phœnix has a very nice hotel in the Adams House. At Eddy there is a fair hotel, but I am told that the dining service is miserable. At Tucson there was a nice little hotel, but I hear that the proprietor has moved to El Paso. It is to be hoped that El Paso will gain by this change.

Las Vegas Hot Springs is probably the best place for the patient with means. There is a large sanatorium there, run on the hotel and cottage plan. A consumptive can go there and spend the entire year in comfort. The Catholic will find at El Paso the Hotel Dieu, a modern, up-to-date hospital and sanatorium of which he can well be proud. Ground has just been broken at Roswell for a sanatorium and it promises to be a great success. Roswell is a coming town. At Alamogordo I found the most comfortable hotel in Arizona or New Mexico. It is a small house, but clean, and the dining service is excellent.

It thus practically resolves itself to the necessity of the consumptive procuring board with private families, keeping house, or having miserable rooms with miserable meals at miserable restaurants. I want to make one exception in regard to restaurants, and that is, wherever there is a Harvey eating house one will get first-class meals. Harvey makes a business of superintending the meal service on the Santa Fe system, and his meals are excellent.

In El Paso I know of only one good boarding-house. In Albuquerque there are said to be several. Patients reaching any town had better go to a European-plan hotel and get meals outside. They can then inquire for and find boarding-places. Examine the railroad cards and if any place has a Harvey house, go there. A woman can always feel safe in going to a Harvey house.

Throughout Arizona and New Mexico one will find society of the best sort. The pulpits are often filled with educated and refined ministers here for their health. It is the same with all the professions, and one need not fear that he will not find cultured and refined people, for they are everywhere though they are sick. The poor man must come prepared for exorbitant charges. From the start he had better have his own home or be sure of his friends. All kinds of attractions are held out to settlers, but one must bear in mind that a farm cannot be commenced here for a small sum as water alone is a big item of expense. There is not a drop of water near irrigable land in either Territory not already pre-empted. The digging of wells is usually a costly experiment. The well-to-do can always make a home with sufficient comforts.

DIRECTORY.

Las Vegas, N. M. Hotels fairly good. Boarding. Patients can remain winter and summer. Altitude, 6418 feet.

Las Vegas Hot Springs, N. M. "The Montezuma;" good attention of all kinds. Patient can rent a cottage and have meals in the main dining-room. Hot baths. Patient can remain all the year. Advanced cases not received. Altitude, 6709 feet.

Santa Fé, N. M. Hotels only fair. Boarding. Greater number of clear days than any place in New Mexico. Summers perfect. Patients can remain all year. Altitude, 7047 feet.

Albuquerque, N. M. Hotel accommodations poor (fine hotel just destroyed by fire) One good restaurant where ladies can go. Boarding. Fine drives. Patients can remain all year. Has best altitude, 5000 feet.

Las Cruces, N. M. Very poor hotel. At the "Alamada," three miles out of town, one will find good meals, though other accommodations are very poor. Part of the year very hot. Winter perfect. Must make arrangements by correspondence before going there. Altitude, 3797 feet.

El Paso, Texas. Several European-plan hotels (others being built). One good boarding-house. Good driving. Fine business town. Good place for the workingman. Summers very hot. Winters perfect. Altitude, 3720 feet.

Deming, N. M. Fair hotel, but good meals. Beautiful country. Small town. Can remain all year. Altitude, 4327 feet.

Hudson Hot Springs, N. M. (near Silver City). Sanatorium. Said to give good care and attention. Can remain all year. Altitude about 5000 feet.

Tucson, Ariz. Beautiful old Mexican town. Beautiful drives. Fair hotels. Boarding. Hot in summer. Delightfully warm in winter. Patients should leave there in summer. Altitude, 2392 feet.

Phœnix, Ariz. Beautiful city. First-class hotel, "Adams House." Boarding. Nicely kept streets

and beautiful drives. Patients should leave in summer. Altitude about the same as that of Tucson.

Prescott, Ariz. Hotels poor. Summers delightful. Altitude about 5000 feet.

Flagstaff, Ariz. Fairly good hotel. Small town. Beautiful country adjacent. Grand Cañon of the Rio Grande sixty miles away, and the San Francisco Mountains nearby with an altitude of 12,000 feet. Fine summer excursions. Altitude of Flagstaff 6862 feet.

Alamogordo, N. M. Hotel first class, though small. Small town, eighty-six miles from El Paso. Hot summer. Stopping place en route to Cloudcroft. Altitude about 4400 feet.

Cloudcroft, N. M. Fourteen miles from Alamogordo in the Sacramento Mountains. Six thousand feet elevation. Used as a resort in summer by people from Western Texas. Said to furnish first-class meals. Summer resort only. Ride on mountain railroad very fine.

Eddy, N. M. Fair hotel. Small town. Altitude about 4000 feet.

Roswell, N. M. Poor hotels. Boarding. Will have a fine sanatorium for consumptives, to be opened this winter. Hot summers; delightful winters. Beautiful drives. Surrounding country good for the poor man to get a start. Altitude about 4000 feet.

STEATOSIS OF THE LIVER AND COAGULATION NECROSIS; A FURTHER CONTRIBUTION TO THE YELLOW-FEVER DISCUSSION.

By FELIX VITALE, M.D.,
of Coytesville, N. J.;
formerly lieutenant-surgeon in the Italian army; ex-forensic physician to the city of Montevideo, Uruguay.

Drs. Reed and Carroll, in their recent article in answer to Professor Sanarelli, stated that a complete report on the comparative experimental pathology of bacillus icteroides and bacillus cholerae suis would be formally presented by them in the near future to the Surgeon-General and would without delay be made public by him. While waiting the completion of their work and its report I have felt that there are certain points in the present controversy with regard to the specific cause of yellow fever that deserve further elucidation. These points have special reference to the steatosis or fatty degeneration of the liver that has been described as specific to yellow fever.

Drs. Reed and Carroll (Medical News, September 9, 1899) say: "Sanarelli speaks as if yellow fever were the only condition in which fat is found in the liver cells. It is hardly necessary to remark that it may be present in considerable quantities in the livers of comparatively healthy individuals. Steatosis may mean little or much; it does not necessarily imply degeneration." Later they say: "Sanarelli displays profound ignorance of the pathology of coagulation necrosis," and finally in their discussion of the pathological lesions found by them in the liver of a soldier who had died from yellow fever they failed to find "the acute steatosis upon which Sanarelli lays so much stress" and leave it to be concluded that it is not pathognomonic of the disease. While waiting for Sanarelli's own answer to these imputations I think it only due to his American readers to point out a rather obvious answer to them and at the same time to give certain details of some work on the subject of fatty degeneration during which I had the privilege of being present in his laboratory at Montevideo.

I must say that Drs. Reed and Carroll's declaration seems to assume on their part no very extensive acquaintance with Sanarelli's work during these last few years. For instance, as regards the first assertion, that Sanarelli thinks that fat is produced in liver-cells only in yellow fever, he published an article in the *Centralblatt für Bakteriologie*, No. 10, page 382, in which he tells of observations made on fatty degeneration as produced by various infectious diseases. It is preposterous to assume his ignorance of a subject like this since, of course, it is well known that steatosis may occur from a large number of causes and that it may be entirely physiologic and not due at all to pathologic factors. It occurs in animals as well as in men without positive disease as the well-known artificially produced fatty goose livers (*foie gras*) of the table testify. Besides other lesions fatty degenerations of liver cells are produced by practically all of the infectious fevers. Hemorrhagic smallpox causes a distinct hepatic steatosis, typhoid fever and cholera are associated with a certain amount of it, and the diphtheria toxin is noted for having an intense steatogenic power.[1] Above and beyond all these, however, is the specific steatogenic power of the bacillus icteroides, its power of producing an intense fatty degeneration of the liver cells of its victims. This degeneration is so widespread and so acutely produced by the bacillus icteroides that it can only be compared with three other processes, namely, the fatty degeneration of the liver found after actual yellow fever, that noted after

[1] Besides bacterial toxins there are, of course, other poisons that produce fatty degeneration. Alcohol and lead are the most common and best known. In my forensic practice in Montevideo I once had in a boy a fatal case of poisoning with anilin oil in which icterus occurred during life and I found fatty degeneration of the liver post-mortem. To make sure for medico-legal purposes that these two phenomena, the icterus and the fatty degeneration of the liver, were really due to the anilin oil we made a series of experimental observations on dogs, using 30 to 40 centigrams of anilin oil to the kilogram of animal. Four out of five died, presenting icterus, and all five after death showed exquisite fatty degeneration of the liver.

phosphorus poison and that produced by the venom of crotalus, rattlesnake poison.

Recognizing the immense value this special steatogenic quality might have in demonstrating the etiological relation of the bacillus icteroides to yellow fever, Sanarelli in his laboratory at Montevideo instituted a series of observations to determine the amount of fatty substance that could be extracted from the livers of dogs immediately after their death from various diseases. It was at these observations that I had the privilege to assist. It was found that in any given disease the extension of the fatty degeneration through the liver substance is never constant. This is true even for the three pathological processes mentioned above which are especially prolific in the production of fatty degeneration of the liver. The hepatic cells of certain animals, even of the same species, are very differently sensitive or resistant to toxins from those of others. The age, size, and especially the breed of the dogs employed in the observation we found made a great difference in the results obtained when the animals were inoculated with the bacillus icteroides. The purer the breed of dog employed the more steatosis was produced.

Havelburg, in his report from Rio Janeiro ("Public Health Reports," November, 1898), pointed out that "the more or less rapid production of the different phases of the disease (yellow fever) is a question of the size of the dose of culture or of toxin." In conformity with this principle we found at Montevideo that the relation between the amount of hepatic steatosis produced and the amount of culture of bacillus icteroides administered was a constant one. It is possible to obtain with repeated doses an even more intense fatty degeneration of the liver than can be produced by phosphorus poisoning. It can be seen not only with the microscope but with the naked eye. The liver presents the orange-yellow color so characteristic of the livers in the cadavers of yellow-fever victims. At times in very acute cases, just as happens in phosphorus poisoning at times also, the intense congestion present obscures this yellow color, but very slight pressure causes the blood to recede and discloses the intense fatty degeneration present.

I await with some impatience the account of the manner in which Drs. Reed and Carroll will determine the comparative steatogenic power of the hog-cholera bacillus and the bacillus icteroides. The method employed by Professor Sanarelli was a very exact one. It consisted in an accurate determination by means of chemical analysis of the amount of fatty substance that could be extracted from the livers of dogs. The quantity of fat in the liver of the healthy dog gave an average dry residue of 6.54 grams per 100. A large series of analyses of this organ after various infections gave the following results: In the liver of dogs dying from cholera the average goes up to 9.44 grams per 100. After death from infection by the colon bacillus it amounts to 10.60 grams per 100; after infection with bacillus pyocyaneus to 11.22 grams per 100; after infection with diphtheria to 14.65 grams per 100; after infection with bacillus icteroides to 22.69 grams per 100. The highest average obtained in any single observation in our laboratory was 32.72 grams of dry residue to 100 grams of the fatty substance, and this was obtained from an animal dead after infection with bacillus icteroides. A very complete confirmation of Sanarelli's results in this matter is furnished by the recent "Report of the Medical Officers Detailed to Investigate the Cause of Yellow Fever." Drs. Wasdin and Geddings report that they obtained from twenty-seven to fifty-three per cent. of fatty matter in the livers of animals that had died from infection with the bacillus icteroides.

Decoreis, in yellow-fever cadavers, in Cuba, noted 22.29 grams per 100 of dry residue from the fat contents of the livers.[1] Canto, at Rio Janeiro and San Paulo, in Brazil, noted 23 per 100[2]. Figueyra, working in Lisbon, noted 31.30 grams per 100.[3] To these may be added the authority of Lacerda, who is quoted by Drs. Reed and Carroll. He says in the *Revista Medica do Brasil*, 29, page 256, 1898: "We do not know another toxic substance of any kind whose steatogenic power is at all comparable to the amaryllic toxin in intensity or rapidity. Even arsenic and phosphorus do not compare with it in their power of producing fatty degeneration of the liver and other internal viscera. Only one poison seems to be in the same class with yellow-fever toxin in this, and that is crotalus toxin—the venom of the rattlesnake. The distinction between these two is that amaryllic toxin is pyretogenic as well as steatogenic, while crotalus poison is only the latter." Dr. Lacerda, in *Archives de Medicine Experimentale* for the present year, speaking of the rapidity with which the toxin of the bacillus icteroides produces steatosis, says that he has seen fatty degeneration already begun only eight hours after inoculation. Mendoza, in the *Revista Medica de San Paulo*, No. 5, 1898, says that in dogs the bacillus icteroides produces lesions identical with those produced in man by yellow fever. He calls attention especially to the fatty degeneration of the liver, the hemorrhagic gastro-enteritis, the albuminuria, and the secondary infections.

[3] *Gazeta Medica do Lisboa.*

In the *Settimana Medica*, No. 19, p. 225, 1899, Foa says: "In the liver of dogs dying from yellow fever experimentally produced by the injection of the bacillus icteroides I found exactly the same lesions as those which I have frequently studied in yellow-fever cadavers. By means of injections of the bacillus icteroides directly into the liver parenchyma I have obtained hepatic steatosis resembling in every particular that of human yellow fever, and accompanied like it by jaundice of the tissues." Observations of the same kind might be quoted from Della Rovere, Belfanti, Bruschettini, and Cesaris Demel, men whose reputations in Italy as impartial observers are very well recognized, but I do not wish to weary the reader.

The specific steatogenic power of the bacillus icteroides has, I think, been amply established by the observations quoted in detail.

Now as to the question of Sanarelli's ignorance in the matter of coagulation necrosis. Some of his most delicate work has been done on just this subject. This from his observations on the livers of guinea-pigs is a good example: "In guinea-pigs the hepatic cell is very resistant to the toxin of the bacillus icteroides. At most this poison produces a granular turbidity of the protoplasm with certain phenomena that point to cellular necrosis, but it rarely gives rise to any characteristic process of fatty degeneration." Then in connection with the livers of rabbits he makes this observation: "The cellular stroma is often compressed and reduced in size. In certain portions the protoplasm of the cell is rendered not granular but vacuolar, and seems actually reduced in amount. In the perilobular tissue there is always infiltration to be observed and at times this is considerable. In rabbit livers there is just the beginning of steatosis but it is very limited in amount." In the livers of dogs he notes the following appearances: "The hepatic columns between the capillaries are reduced to small, narrow bands made up of cells that are completely altered in form and practically all reduced in size. They are cloudy in appearance, granular, and in some parts completely destroyed, converted into globular masses of material not to be recognized as cells." (*Annales de l'Institut Pasteur*, 1897. *Annals of the University of Montevideo*, vi year, vol. xi, pp. 76, 86–100.)

It is evident from these quotations that to speak of Sanarelli's ignorance of coagulation necrosis and its relations to steatosis is entirely uncalled for and gratuitous. It is no wonder that he read with surprise Drs. Reed and Carroll's declaration that he had not made any mention of these most striking lesions when they seemed to refer in their first article to spots of necrosis easily visible to the naked eye.

There are certain necrotic lesions of the liver that are very similar in a number of infectious diseases. Hanot noted in the livers of patients dead from practically all of the infectious fevers, whitish spots with identical histological characters.[1] He did not, however, because of this announce that there was reason to think of an identity of virus in the various infectious diseases, yet it would seem to be on some such insecure ground as this that Drs. Reed and Carroll would argue the identity of the bacillus icteroides and the bacillus choleræ suis, because forsooth both produce cellular necrosis of the liver.

There would seem to be a tendency here on the part of Drs. Reed and Carroll to confound necrosis in general with coagulation necrosis, two things that I need not say are utterly distinct. All the pathological anatomists are not agreed as to what coagulation necrosis is in essence or as to its cause, but all make it a thing apart from necrosis. It would seem that microbic toxins sometimes act upon the cell *d'emblée*, *i.e.*, without producing gradual destructive effects. The cell is fixed rather than killed and presents a vitreous substance that often does not take the ordinary stain but requires the double stain, hematoxylon and eosin. A single lesion such as cellular necrosis ought certainly not be made the basis for declaring any two diseases identical, especially when they are differentiated by so many other points as are the affections produced by the hog-cholera bacillus and the bacillus icteroides. In their first article this production of liver necrosis was practically the only reason advanced by Reed and Carroll for thinking the two bacilli the same, though they now admit (MEDICAL NEWS, September 9, 1899) that a similar lesion occurs in many infections. What should be taken into consideration are the many points of distinction in the pathologic effects produced by the two forms of bacilli.

Welch and Clement even with attenuated cultures of the hog-cholera bacillus when injected intravenously always obtained the lesions produced by the virulent form, namely, hemorrhages, necrosis and diphtheritis. According to them similar observations were made by Theobald Smith.[2] Silberschmidt noted miliary abscesses four or five times in the livers and spleen of rabbits. At the point of inoculation abscesses occurred and sometimes they were large. After injection into the ear there was often edema of the auricle and swelling of the tissues over the jaws and at the back of the neck and this was often followed by deep and extensive abscesses in these regions. Often there occurred purulent pleurisy on the side on which the inoculation was

[2] Welch and Clement, "Hog Cholera and Swine Plague," p. 13, 1894.

practised and more or less frequent abscesses at the base of the lungs with concurrent hepatization. The abscesses constantly gave pure cultures of the hog-cholera bacillus.[1]

In the hundreds of rabbits that have been sacrificed during the experimental observations on the bacillus icteroides neither Sanarelli himself nor any of the other observers, and their name is legion, has ever called attention to such hemorrhages, necrosis and diphtheritis of the intestine as occurs after inoculation with hog cholera. A subacute infection with the bacillus icteroides, though this form of infection is not infrequent in experiments with the hog cholera bacillus, was observed only by Foa and then only under the influence of antiamaryllic serum.

Pulmonary and hepatic abscesses and purulent pleurisy are completely unknown in rabbits infected with the bacillus icteroides and I have yet to hear of a single case in which Sanarelli's bacillus was ever isolated from the purulent contents of a pericardial sac. These lesion that I have mentioned are surely at least as important as the simple foci of necrosis noted by Reed and Carroll. As to the diphtheritic lesions of the intestines, I think that my citation of a case in the MEDICAL NEWS for September 23, 1899, in which such lesions occurred in the intestines of hogs after the ingestion of bacillus icteroides, will serve to show how dubiously significant they may be.

It must be borne in mind that the steatosis and cellular necrosis said to occur in the liver of dogs after inoculation with the bacillus icteroides develop very rapidly. An observation made on dogs inoculated four or five months before their death, such as is reported by Drs. Reed and Carroll, has no significance for the question of acute steatosis. In such a length of time the streptococcus of erysipelas may produce a steatosis as profound as that of the hog cholera bacillus. It is the acuteness of the fatty degenerative process, it must be remembered, that distinguishes yellow fever and phosphorus poisoning from other agents that produce hepatic steatosis. Moreover, it must not be forgotten that when the animal survives for some time, the degenerated cell revives and with almost as much rapidity as the degeneration took place,[2] so that it is not impossible that in the course of the inoculations of a dog extending over four to five months in Drs. Reed and Carroll's observations, there was a series of degenerations and regenerations in the hepatic cells. Drs. Reed and Carroll do not say what method they employed to estimate the fat in the livers of the animals they had under observation. For comparative purposes as to the effect of the bacillus icteroides and the bacillus of hog cholera, it certainly is not enough to make a microscopic examination only, and we are told nothing of the chemical analysis which should have been employed in order to make the estimation of the fatty material present exact.

The assumption that Sanarelli and his school know nothing of fatty degeneration and of cellular necrosis that marked the *tour de force* of Drs. Reed and Carroll's argument would really be amusing were the subject not so serious. Surely they will give us credit for a certain minimal knowledge of these subjects, in which case it would have been impossible for us to have fallen into the error they point out.

BETA-EUCAIN AS AN ANESTHETIC IN EYE NOSE, AND THROAT WORK.[1]

BY WILLIAM H. POOLE, M.D.,
OF DETROIT, MICH.

EVER since the anesthetic action of cocain was discovered and its use made practicable by Niemann and Koller there has been a hope in the hearts of many practitioners that some other equally efficient but less toxic drug would be evolved from the chemist's laboratory. As the dangerous condition frequently following the use of cocain, even in the hands of the most careful operators, gave birth to the unexpressed as well as oft-reiterated desire for some more safe anesthetic, so, too, it spurred on the chemist in his laboratory researches until success has seemingly crowned his latest efforts, and we have the product beta-eucain as the result. Exception may be taken to the foregoing on behalf of the ophthalmologist pure and simple, who has come to regard it as an axiom that cocain meets every requirement that could reasonably be expected of a local anesthetic; but we must not lose sight of the fact that the great majority of ophthalmologists include nose and throat diseases in their practice, and while they may have no fault to find with cocain as an anesthetic in the ophthalmological part of their operative work, yet this does not hold good in their rhinological and laryngological cases. I presume we each and all have had patients who, after a minimum dose of cocain was applied to the nose or throat, grew dizzy, faint, had a pallid countenance, with disturbed circulation, spasmodic action of the heart, great dyspnea, and final collapse into unconsciousness. I have at different times had such an experience following the local application of the drug, not only in the nose and throat, but in an eye case which will be referred to later on. Hence arises the interest I feel in this newer product which

[1] Read before the Surgical Section of the Mississippi Valley Medical Association at Chicago, Ill., October 6, 1899.

in my experience has proven equally efficacious as an anesthetic without producing the toxic effects above enumerated.

There are two entirely distinct products sold as eucain, the distinction being made by naming one alpha eucain, the other beta-eucain. Beta-eucain is the one I am more particularly interested in at this time, though clinically there is no distinction necessary excepting that of irritation to the eye. It was on account of this irritation in the use of eucain A that eucain B was brought out and made available, as in the latter the irritant effects are minimal. Eucain B is a stable chemical compound which is not decomposed by heating even up to the boiling point. This is a decided advantage over cocain solutions which do not keep well and are decomposed by heat, whereas the eucain solution can always be speedily made aseptic by boiling without in any way destroying the activity of the drug.

There are three conditions that must be fulfilled before a drug can lay claim to being an ideal anesthetic, *viz.*, the reduction of pain to a minimum, increasing the facilities of the operator to the maximum, and producing no unpleasant after-effects. As cofactors of these requirements I must consider the method of application, temperament of the patient, and skill of the operator. First, as to the reduction of pain or producing anesthesia, I have found from my experiments, both clinical and in private practice, that we possess in eucain an anesthetic by the aid of which we can render the mucous membrane so insensible that local operations may be performed without suffering on the part of the patient. The mode of applying the solution governs to a great extent the degree of anesthesia, and consequent comfort to both patient and operator. Instillation is the preferable method in eye and ear cases, while in those of nose and throat better results will be obtained from contact with a saturated pledget of absorbent cotton. Spraying the nasal cavity, be it ever so skilfully done, will not prove as satisfactory as a properly shaped and carefully applied cotton pledget. By properly shaped I mean spindle shaped, which is easily made by lightly twisting the cotton around the end of a probe, saturating it in beta-eucain solution, and placing it in position so that it lies parallel with the turbinate. The probe is then withdrawn, leaving the cotton *in situ*. In throat work swabbing with cotton, holding the cotton in contact with the part, and renewing the application produces satisfactory anesthesia.

The strength of the solution necessary to secure anesthesia depends largely upon what is to be done and the region affected. In ophthalmologic cases a two-per-cent. solution produces satisfactory anesthesia fully equal to that obtained by a four-per-cent. cocain solution. In addition to its use preparatory to operative procedure, it serves an excellent purpose in overcoming the irritability arising from applications of silver and copper to the conjunctivæ, the removal of foreign bodies, and many other conditions. This two-per-cent. solution is admirably serviceable also in all cases in which a thorough examination of the nares, pharynx, or larynx is necessary, where, through irritability or hypersensitiveness of the parts, such an examination would otherwise prove well-nigh impossible. In those patients who are intolerant of laryngoscopy as well as in some in whom irritating applications have to be made to the larynx, this solution is of great service In operations in the nasal chambers the nasopharynx, the pharynx, and larynx a solution of from four to ten per cent. is required to secure satisfactory results.

The second condition necessary to an ideal anesthetic is that it shall aid the operator to the fullest possible extent. In discussing this point I shall necessarily have to consider (*a*) the temperament of the patient, (*b*) the rapidity, intensity, and extent of the anesthesia, and (*c*) the systemic as well as local action of the drug.

(*a*) Regarding the temperament of the patient, we have each of us undoubtedly met with patients of that peculiar mental and physical combination of make up that they involuntarily were a great help or a great hindrance to the operator.

(*b*) As to the rapidity, intensity, and duration of the anesthesia, I have found that there is a great difference in individuals as to the time required to secure satisfactory anesthesia; but in the majority of cases the effect of the drug has been noticeable in two or three minutes, anesthesia being obtained in from five to ten minutes after the application of the solution was begun and lasting from eighteen to twenty minutes.

(*c*) In regard to the systemic action of the drug, I have yet to see the first case in which it has produced any heart depression or other objectionable symptoms indicating systemic poisoning.

Locally the action of the drug differs essentially from that of cocain in nearly every respect, except that of producing anesthesia. In this it is fully as efficient and in some instances more so. While it is obvious that an exact comparison of the action of the two drugs is a matter of some difficulty, owing to the idiosyncrasy and varied sensitiveness to suffering on the part of different patients, yet there are certain local effects produced which are decidedly characteristic of each. In my experiments with eucain B. I made use of a two-per-cent. distilled water solution

in three different classes of eyes: those practically normal, those that were inflamed, and in operative cases. Instillation of an equal strength solution of the two drugs in each eye was made, with the result that some patients complained of more smarting from the cocain than from the eucain, while others claimed the reverse. Many of them experienced no discomfort at all.

As to how the ischemia of cocain, and the lack of it or possibly its opposite, the slight hyperemia of eucain is produced is not within our province at this time to determine, but it is certain that the instillation of eucain B. solution is not followed by that marked whiteness, as if frozen, and hypotonicity of the eye produced by cocain, neither is the eyeball projected forward with widely dilated pupil. In contrast with this the eucainized eye presents a normal appearance. In about half of my cases only was there a moderate degree of vascular dilatation without forward protrusion of the eyeball and without mydriasis, which renders it valuable in operations upon glaucomatous eyes in which the cocain mydriasis is inconvenient. One great advantage in favor of eucain is that the accommodation is not affected and the pupil remains unchanged, promptly reacting to light stimulus and convergence. Perfect insensibility of the cornea and conjunctiva is obtained in from two to three minutes, and no cloudiness of the cornea has been observed nor could I observe in the eucainized eye those wavy, broad lines in the cornea so frequently seen in the cocainized eye.

I have made use of beta eucain in treating quite a few eyes that were in an inflamed condition, such as cases of foreign bodies in the cornea, keratitis, corneal ulcerations, episcleritis, and iritis. In these several conditions the anesthesia was fully as satisfactory as under cocain, except, possibly, in the case of iritis, in which there is more congestion of the anterior vessels. Here the patients experience greater relief from the cocain, owing to its vasoconstrictor action.

I have made use of the drug in the following instances in operating on the eye, ear, nose, and throat, obtaining fully as satisfactory obtunding of the sensibilities as could be desired, or as was obtained under cocain, and in two cases which I will specially mention the use of cocain was debarred on account of the alarming symptoms which set in under its use, the patient subsequently being operated on under eucain without the slightest untoward symptom arising. *Eye.*—Chalazion extirpation, 5 cases; entropion, 1; trachoma, 2; opening the lacrimal duct, 3; pterygium, 1. *Ear.*—Furuncle of the auditory canal, 2; paracentesis of drum membrane, 1. *Nose.*—Hypertrophied turbinates, galvanocautery operation, 7; nasal polypi, 3; nasal spur, 2; foreign body, 1. *Throat.*—Abscission of uvula, 2; excission of tonsils, 3. In the eye cases a 2-per-cent. solution was made use of, while in the other cases a 4 or 8 per-cent. was deemed advisable.

The third condition or attribute that our ideal anesthetic should possess is that it should give rise to no unpleasant or untoward after effects. In my use of eucain this has been the case. Following the anesthesia I have found the disturbances of sensation much less lasting, less defined, and less unpleasant than when cocain was used. In fact, the greatest possible difference exists in regard to the toxic action of cocain and eucain, as was noted in the two following cases, the reports of which are taken from those above mentioned as illustrative of this point.

H. M., aged thirty-eight years, had been troubled with obstructive breathing in the nose for three or four years, which had been getting worse. He had used a spray of Dobell's solution for some time, but with only partial relief. Externally the contour of the nose was changed, being rounded out toward the cheeks on each side, altering the expression of the whole face. On rhinoscopic examination several polypi were discernible, hanging from the attic of the nares. After cleansing the field I applied a four-per-cent. solution of cocain to the right naris for the purpose of removing some of the growths with a snare. In two or three minutes the patient gave evidence that he was being affected by the drug by his rapid and loud talk and gesticulations. This was followed by great depression and dyspnea, the pulse becoming weak and slow. I placed him in a recumbent position and with the aid of amyl nitrite soon brought about his recovery. The next day, and several different times afterward, I used a four-per-cent. eucain solution, removing in all twenty-three polypi, and destroying their bases with the galvanocautery under eucain, without the slightest trouble manifesting itself and with perfect anesthesia.

W. K., aged thirty-two years. Multiple chalazion. Left eye, one on inner half of lower lid, one on outer half of upper lid. Instilled cocain solution in a few minutes caused such alarming syncope that I was obliged to place him in a horizontal position and use amyl nitrite and ammonia to bring about his recovery, and of course, suspended operations for that day. Three days following this, however, I extirpated the chalazions under eucain without any discomfort to the patient other than a slightly disagreeable hot taste caused by some of the eucain which had passed down the lacrimal duct. About a month later I removed another chalazion from his right upper eyelid under eucain without unpleasant effects.

I have cited these two cases simply to emphasize

the fact that there are cases, whether due to idiosyncrasy or not, in which cocain is precluded, and if eucain were of use in none other than these it would still be of decided value.

Conclusions.—1. Eucain is decidedly less toxic than cocain, therefore superior to it.

2. Its aqueous solutions keep well and can be sterilized by boiling without destroying the activity of the drug.

3. It produces anesthesia equally well and sometimes better than cocain.

4. It is superior to cocain in that it does not cause heart depression or other unpleasant effects.

5. It does not cause mydriasis or disturbances of accommodation, which is an advantage in some cases.

6. It is less dangerous to the cornea than cocain inasmuch as it does not cause desquamation of the superficial epithelium.

CLINICAL LECTURE.

THREE INTERESTING HEART CASES.[1]

By CHARLES ROSS JACKSON, M.D.,
OF NEW YORK;
ASSISTANT IN GENERAL MEDICINE AND DISEASES OF THE CHEST IN THE NEW YORK POLYCLINIC.

Case 1.—The patient is a well-built man, about forty-four years of age, but pale and haggard in appearance. His history is one of articular rheumatism five or six years ago and sequential endocarditis. When he is stripped one can see the pulsation of the carotid and brachial arteries, the latter, when his hands are held up being visible at least across this room and even further, about forty feet. On closer inspection one can detect pulsations in the temporal and radial arteries; the capillary pulse is marked. A better exhibit of the water-hammer or Corrigan pulse is impossible. The apex beat is fairly strong and circumscribed in the seventh space one inch outside the nipple line. Beneath the end of the sternum a strong impulse is noticed, due to the action of the hypertrophied right ventricle. Both subclavian arteries are seen to heave and throb to an excessive degree during arterial systole. Palpation proves the strong action of the left and right ventricles but does not detect thrills over any part of the heart area. The systole is found to be 84 per minute. Over the carotids a marked thrill is detected, systolic in time. Over the subclavians noticeable heaving is felt, and a systolic thrill of truly immense amplitude. This thrill is most pronounced over the left subclavian but is detectable in the upper portion of each brachial artery. The pulse is collapsing at the radials, but of great volume at the height of the arterial wave.

The collapsing quality of the pulse gives rise to an interesting sensation at the brachial artery near the elbow which, so far as I am aware, has not yet been described. Personally, I have found it only in pulses with the water-hammer quality in marked degree. Place the palmar surface of the left thumb vertically over the left brachial artery, the arm being extended. Make light pressure and notice the curious instantaneous tap with no precursory or succeeding sensations whatever. This tap is not detectable over the radials or the carotids. It is presumably due to the collapsing artery not being followed by the thumb in its inward movement. The vertical thumb is held outward by the surrounding tissue, and the artery collapses so suddenly that the thumb cannot follow it as can the fingers elsewhere. This tap or "hit and gone" sensation is interesting at least.

By the rate and strength of the cardiac systole it has been determined that hypertrophy predominates over dilatation. Percussion shows absolute dulness extending at least one inch to the right of the sternum and one inch beyond the left nipple line downward to the seventh space. Superiorly, it extends to the upper surface of the third rib. This is an extremely large area of dulness and denotes much enlargement of both left and right ventricles. Auscultation reveals a low, short, systolic murmur at the apex, heard best by means of a stethoscope with a rubber tubing. The heaving impulse if carried to the ear by a stiff instrument will overwhelm this murmur. It may be traced laterally and is audible in the posterior mitral area. In addition to this murmur of mitral regurgitation a low and indistinct diastolic murmur is detected over the second right interspace. It is transmitted down the sternum and is heard best at the left fifth intercostal space. A little to the left of this area is another murmur of slighly different pitch and quality and of decidely different time, it being systolic. These two murmurs shade off into one another, and might be mistaken for a single murmur were it not that one is diastolic at its maximum point, the other systolic. The diastolic murmur conveyed downward to this area is aortic regurgitant in origin and follows the usual course of these murmurs when pronounced. The systolic murmur is due to insufficiency of the tricuspid valves.

Elsewhere over the heart proper there are no murmurs, but at the second right interspace near the sternum there is a harsh rasping murmur systolic in time. In conjunction with the thrill at the carotids and the murmur which is transmitted there we might presume this murmur at the second right space to be due to aortic stenosis were it not that this sphygmographic tracing which I have recently taken shows us besides the quick and long down stroke of aortic regurgitation an absolutely vertical up stroke of great height. This strictly vertical ascent and exactly pointed summit disprove the presence of any actual stenosis at the aortic orifice at this date. When stenosis exists there must be less rapid filling of the arteries than under other conditions. The ascending stroke of the tracing then occupies an appreciable fraction of a second and is registered as slightly inclining. While there may have been stenosis at some time the present condition is probably one of dilated aortic orifice following the wear and tear of the increasing insufficiency. In such a condition there is usually dilatation of the aorta also at the orifice. This murmur may be caused by vibrations, generated

[1] A clinical lecture delivered at the New York Polyclinic Medical School and Hospital.

primarily by extremely roughened or deformed valves, or by the exit of blood from the ostium into an artery of increased caliber. The murmur must be regarded then as generated at or about the aortic orifice without any actual stenosis.

Following along the course of the aorta one hears over the sternum a louder, rasping, extremely disagreeable murmur. This increases toward the left and is most audible over the left subclavian artery where the thrill is best located. This murmur is heard through the stethoscope in both radials to a pronounced degree. It is doubtless endo-aortic, and due to changes in caliber, or to extreme roughening of the artery, or both. No actual stenosis can exist here in the aorta either, as evidenced by the tracing. The changes are doubtless those of dilatation and roughening. The carotid thrill can be induced by the great vibrations generated by this aortic condition as well as by stenosis at the orifice. To my mind the murmur at the second right costal cartilage and this more exaggerated one over the course of the aorta and subclavian are related, and are due to the effects of aortitis, *i. e.*, dilatation, roughening, etc. The thrills are of the same primary origin as the murmurs but they depend upon vibrations of less speed and greater amplitude than those which produce murmurs.

The treatment in this case has been extraordinarily successful. The first year or so the patient took large doses of iodid of potash, as much as 50 grains, three times daily, with only slight relief. Then treatment with nitroglycerin was inaugurated and has since been carried out. The arterioles are kept completely unlocked almost constantly. When the tension is allowed to become high through carelessness or from other causes he becomes uncomfortable and is subject to attacks of extreme dyspnea and pain with distressing headache. His constant use of the nitroglycerin has inured him to its action and very large doses are required. He averages about 2 grains of the drug a day. I have given ¼ of a grain in two hours during an anginal seizure with greatly increased arterial tension. In these large doses lie his salvation. There doubtless is marked degeneration of the aortic walls and probably of the coronary arteries. The nearly constant dilatation of the arterial system is of course participated in by the cardiac blood-vessels, and permits of excellent myocardial nutrition. The heart muscle being still so well nourished no cardiac tonics are called for. His condition is better than formerly but the prognosis is of the gravest. His liability to sudden death is very great.

Case II.—The second patient, a man forty years old, was before you two weeks ago. At that time he gave the history of a slight rheumatic attack some years previously. He had been perfectly well since then, until three days before coming here, at which time he was overcome by sudden dyspnea, great weakness, vertigo, and edema of the legs. An examination showed that his lungs were normal with the exception that there were some signs of edema posteriorly and below. His heart was much enlarged, the dulness extending one inch to the right of the sternum and 1½ inches to the left of the mammary line in the sixth space, where the apex was located by auscultation. You remember that the impulse was then neither visible nor palpable, and that no murmurs were present owing to the extreme weakness of the heart action. The pulse rate was 140 and difficult to count; the first and second sounds were indistinguishable from one another; in other words, the cardiac cycle resembled that of the fetal heart. The urine was scant and slightly albuminous.

Having excluded the possibility of pericarditis with effusion the diagnosis of great acute cardiac dilatation was made. I said that although no murmurs were present the lesion was probably an aortic stenosis or mitral regurgitation. The possibility of an uncomplicated mitral obstruction was excluded owing to the enlargement of the left ventricle. An aortic regurgitation might have been present, but this was hardly likely as the pulse in the carotids, where it was visible, was not collapsing as one would expect in aortic insufficiency. Then again, aortic insufficiency with a pulse of 140 would not permit the patient to rise from his bed without the probable occurrence of syncope.

The treatment was vigorous, consisting of the administration of half an ounce of the infusion of digitalis reinforced by one twenty-fourth of a grain of strychnin four times daily. The infusion was chosen for its double action on the kidneys and heart. Three days later his urine was not so scanty, and his pulse was somewhat stronger. The treatment was continued until his next visit, just a week from his first appearance. The urine was then abundant, about two quarts in the twenty-four hours. His pulse was 100 and much stronger. Strychnin was discontinued, and the infusion of digitalis continued with the addition of five grains of iodid of potash three times a day. The potassium iodid was given solely as a means of unlocking the arterioles and overcoming the tension in the arteries which was excessive. I have already explained the action of the iodids, as brought to notice by Balfour, in my previous talks on the employment of the vasodilators in heart disease.

To-day we find the area of dulness somewhat less, the apex beat visible and palpable about three-quarters of an inch outside the nipple line in the sixth space. By auscultation one can detect the great improvement in the heart sounds, the systolic sound being easily identified and of fair tone. A feeble systolic murmur is heard at the apex area and posteriorly, evidence of mitral insufficiency. Over the right second space is a very low-pitched systolic murmur probably due to aortic stenosis, but one must be cautious in so pronouncing it as these murmurs are sometimes produced in the anemic heart, as I have already demonstrated. The fact that this murmur is not accompanied by a thrill and is not conducted to the carotids does not by any means exclude stenosis, but means that it is too feeble to have the usual concomitant vibrations and areas of transmission. The sphygmogram shows a pulse of high tension but fair quality. The ascending stroke shows an angle of about 30° from the vertical, is distinctly slow in its ascent and rounded at the top. This, with the basic systolic murmur and the great enlargement of the left ventricle (greater than is usually seen in uncomplicated mitral insufficiency) makes the

diagnosis of some stenosis at the aorta probably correct. The pulse is now 80. Over the tricuspid area there is a systolic murmur of a rasping character, due to regurgitation at the right auriculoventricular orifice. This regurgitation is easily proved by allowing the patient to assume the semirecumbent position when an impulse is detected in the right jugular vein synchronous with ventricular systole. A slight diastolic pulsation can also be detected. This is not due to regurgitation at the orifice but to partial emptying of the right auricle upward into the veins on auricular systole, during cardiac diastole. This jugular movement, diastolic in time, is frequently seen in persons with hard working hearts when in the reclining position; the systolic pulsation never, unless the tricuspid leaks, and it is even then not always demonstrable.

The patient's condition is now fair, the edema is nearly gone, the urine is large in quantity. Not wishing to force the heart and kidneys so excessively now, instead of the infusion we will give him 10 drops of tincture of digitalis three times daily, which is a proportionately smaller dose than half an ounce of the infusion. The potassium iodid being well tolerated and the tension still too high we may slightly increase the dose to 8 grains three times a day. The patient must be carefully watched now; the temporary discontinuance of digitalis may be indicated at the next visit. With such dilatation and a pulse only as low as 80, with the passage of large amounts of urine there need be no fear from the use of the drug as yet.

These cases of acute failure of the cardiac muscle, the acute, severe breaking of a previously good compensation are always grave. One never knows how the myocardium may react to stimulation. What may appear to be a recoverable attack may be the onset of a slowly ingravescent terminal asystole. Treatment must be vigorous.

Now that the patient has left the room I will state that the prognosis is good for this attack, but bad for future ones. Sudden development of such cardiac symptoms without previous suspicion of heart disease points to a very sudden exhaustion of the muscle, and particularly when following the lesions which he has, is of poor prognosis. The complete giving way of the right auriculoventricular orifice is already assured and general venous stasis will at times supervene. However, the patient may continue for a long time under treatment without another collapse. To fix the date of final invalidism is naturally difficult in heart cases, but in this instance it is not far away.

Case III.—The third patient, a man forty-seven years of age, gives the history of having had attacks of pain in his chest and left arm for about ten years. During the periods of pain he also suffers from dyspnea. Five years ago he lost his voice rather suddenly and his condition was such that it necessitated his stopping work. At present he is about as he was then, according to his statement. He gives a specific history dating back twenty years and states that the diagnosis of aneurism was made a decade ago. He has been under observation at this clinic for about one year. His weak, cracked voice makes us suspicious of tubercular or specific laryngitis, or of paralysis of a cord. Examination of the larynx shows the left cord fixed in adduction, the cadaveric position. This is due to paralysis of an abductor by pressure on the recurrent laryngeal nerve, frequently by aneurism. It will also be noticed that the left pupil is fixed in contraction, responding neither to light nor accommodation, a myosis due to pressure on the sympathetic nerve, also pointing to aneurism. His metallic, paroxysmal cough is another pressure symptom. Inspection of the chest reveals nothing except the apex beat within the nipple line at the fifth space. There are no other pulsations of the chest visible. Palpation shows that the left pulse is slightly retarded; the rate is 70, the tension normal. There is a systolic thrill in the right carotid. Percussion reveals an abnormal area of dulness extending from the right margin of the sternum at the second cartilage upward to the first rib and across the sternum for about one inch and a half to the left. On this side it extends downward to the third rib forming a somewhat pear-shaped area. There is a dull area posteriorly between the second and fifth ribs near the left side of the column. The heart is quite normal in its sounds, with the exception of an accentuation of the aortic second sound which, if no evidence of general high tension be present, is a very valuable guide in aneurismal cases. In this instance the accentuation is not at all marked, implying but little dilatation of the aorta in its first division. At the second right space a low-pitched systolic murmur is detected which extends across the sternum and is lost to the left. There is also a transmission of this murmur up the right carotid. Now with a low-pitched murmur at the second right space, and a thrill and murmur systolic in time in the carotid one might be led to make a diagnosis of aortic stenosis, as these are classical symptoms of stenosis according to some observers. But as this thrill and murmur have to my certain knowledge been present a long time and the left ventricle is *not* enlarged one can positively exclude stenosis. It is an intra-aortic murmur, pure and simple, and denotes change of caliber or roughening or both.

The diagnosis of dilatation of the aorta (aneurism) can safely be made. The lesion is in the transverse and the commencement of the descending portion of the aorta, as is evidenced by the area of anterior and posterior dulness and the pressure symptoms in the larynx and eye. The presence of dysphagia and tracheal tugging with not much accentuation of the second sound aid in locating the aneurism. The present good condition of the patient and the stationary character of the symptoms, with the absence of detectable impulse lead to the opinion that there has been pretty firm fibrinous consolidation of the sac. The treatment for years has been with iodid of potash in large doses for long intervals. When the pain becomes severe he seeks treatment and is quickly relieved by this remedy. Besides its supposed action on the arterial walls the drug affords him relief, probably by dilating the arterioles and thus diminishing pressure within the aneurismal area. He has had no other treatment not even rest.

The points of particular interest in this case are the pressure symptoms in the larynx and eye, the undoubted intra-aortic murmur and its area of transmission with thrill,

the long duration of the disease, and the absence of other usual symptoms such as hemoptysis. These cases of deep-seated aneurism are extremely difficult to consider from a prognostic standpoint. Rupture of the sac may occur at any moment but the stationary character of the symptoms is at least hopeful. This man has lived an extraordinarily long time already, very much longer than the average one suffering from an aneurism.

MEDICAL PROGRESS.

So-called Typhoid-Pneumonia.—Smith (*Mary. Med. Jour.*, September 2, 1899) draws the following practical conclusions in regard to the use of the term "typhoid-pneumonia": In view of the fact (1) that the majority of pneumonias occurring in the course of typhoid fever are not caused by Eberth's bacilius, but by the pneumococcus, and (2) that asthenic pneumonias with so-called typhoidal symptoms have nothing in common, so far as etiology is concerned, with typhoid fever, it would seem advisable to discard the term typhoid-pneumonia as savoring too much of inaccuracy. For those rare cases in which it can be proved beyond doubt that the pneumonic processes as well as the general typhoid infection are both due to the bacillus of Eberth we still have the term pneumo-typhoid, the use of which, however, should be subject to these strict limitations. Accuracy in terminology is the first step toward a reasonable therapy, and calling conditions by their wrong names must inevitably lead to a less clear-sighted management of them.

Excision and Suture as a Cure for Impermeable Stricture of the Urethra.—Deanesly (*Brit. Med. Jour.*, July 29, 1899) reports a case in which he cured an impermeable stricture of the urethra about half an inch long and situated at the anterior part of the bulbous urethra by resection and suture. He made an incision from the anus to the scrotum and easily exposed the constricting portion. But although the urethra was opened in front of and behind it, it was impossible to pass even the finest probe through the stricture. The strictured portion was therefore resected and the healthy portions of the urethra sutured with six silkworm-gut sutures which were passed through all the coats of the urethra. Other sutures were passed through the outer coats. The catheter was left in position and the urine was exhausted by Cathcart's apparatus. By this means the wound was kept perfectly dry for ten days. The catheter was then removed but was used to draw off the urine several times daily. The operation was very successful and a year later there was no sign of contraction, though a sinus still persisted, due apparently to a silk-worm-gut stitch. There was no leakage of urine, however, either during or after micturition.

The Nature of Black-water Fever.—Dowler (*Brit. Med. Jour.*, July 15, 1899), who has practised in Bengal for some years, states that black-water fever is rare among the natives although they make the misleading assertion that they have passed bloody urine, when it is merely of a high color due to malaria. The disease differs from malaria in the hemorrhagic character of the urine, in the fact that it runs at a lower temperature, seldom above 101° F., in the muscular weakness and prostration, and in the tendency to syncope. In spite of these differences, Dowler questions whether malaria and black-water fever may not both be due to similar if not the same causes.

Management of Pregnancy Complicated by Abdominal Tumors.—Hall (*Jour. Amer. Med. Assoc.*, September 2, 1899) says that the ease with which some patients recover after the removal of abdominal tumors during pregnancy, should not mislead one into the belief that there is no danger of abortion under such circumstances. If it does occur, its risk is greater than at other times, yet this fact should not deter one from an operation which is clearly indicated. Operation is advisable in all cases in which the tumor is small and fixed in the pelvis below the uterus, so that it cannot be lifted out of that cavity. Operation should also be performed if the tumor itself presents complications such as a twisted pedicle or a ruptured cyst. Operation is not to be advised during pregnancy if an ovarian tumor is above the uterus and is too large to occupy the pelvic cavity and does not give rise to important symptoms. The writer advises operation in all cases in which a fibroid tumor occupies the lower segment of the uterus in such a position as to interfere with delivery at full term. The time selected for operation must depend upon the individual case. If the woman has passed the fourth or fifth month of gestation and it is possible to carry her nearly to full term, the question of saving the child must be discussed. If her surroundings are favorable this may be attempted. In many cases the long-continued pressure upon the ureters interferes with the action of the kidneys to such an extent that immediate operation should be performed, else the mother if allowed to go on to full term will be likely to die after the operation from urinary complications. This is even more likely to be the case if the tumor develops in the broad ligament.

Differential Diagnosis of Smallpox.—Corlett (*Nir. Med. Semi-Monthly*, August 11, 1899) insists upon the importance of the recognition of smallpox on account of the harmless appearance of mild cases and on account of the difficulty of maintaining strict quarantine regulations, unless a positive diagnosis is made. All forms of smallpox are essentially the same and the source of contagion no matter how bland is no criterion as to what form the disease will assume in those exposed to it. The typical smallpox lesion is indurated. In typical smallpox or varioloid the most prominent lesions may be composed of small blisters which when punctured absolutely collapse, but in all cases there will be some indurated lesions. In the initial stage smallpox often simulates cerebral meningitis more closely than any other disease. Again, the severe epigastric pains and vomiting have led the physician into thinking that intussusception or appendicitis is present or that the patient had swallowed some poisonous material. In the initial stage smallpox may be mistaken for measles on account of the erythematous eruption which is not infrequently present during the initial fever. In measles the rash appears later, on the third or fourth day of the disease, while the mucous symptoms which are so promi-

nent in measles are nearly or quite absent in smallpox. There is never any induration in the lesions of measles. With the appearance of the eruptive stage the temperature rapidly falls in variola but not in measles. Scarlet fever may be confounded with varioloid but the premonitory symptoms of the former are by no means so severe as are those of the latter. The pulse in scarlet fever is rapid out of proportion to the mild fever. In variola the two agree. The rash of scarlet fever is brighter than that of variola and occurs first on the chest, cheeks, and neck instead of on the lower portion of the abdomen and thighs. The cervical lymphatic glands often swell in scarlet fever, rarely in the early stage of variola. The scarlet tongue so characteristic of the former is absent in the latter. The prodromal rash of variola seldom occurs in young children. Smallpox has been mistaken for impetigo. The lesions of the latter disease which led to this mistake were due to secondary infection of the smallpox lesions by ordinary pus cocci, giving rise to a collection of serum under the epidermis surrounding the encrusted smallpox lesion. Such an error in diagnosis will hardly be made by any one familiar with the two diseases. Chicken-pox and smallpox have often been confounded and in Germany it is still taught that the two diseases are identical. Histologically, however, the lesions have been shown to differ in location, as well as in the manner of their formation. In varicella the superficial strata of the epidermis are principally involved while in variola the first changes take place between the epidermis and the capillary layer of the derma; consequently the lesions in varicella are easily destroyed, whereas in variola it is impossible to rupture the lesions so as to evacuate the entire contents without numerous punctures. In varicella multiple lesions are the rule. In variola the lesions present a uniformity of development. In varicella the lesions are short-lived, lasting but a day or two. In variola a fortnight or three weeks completes the life-history of the lesion. Even in mild cases of variola in which the lesions have a shorter life-history the multiple form character is less conspicuous than in varicella. Varicella is essentially a disease of childhood. It is seldom if ever seen after puberty. Premonitory symptoms of smallpox have more than once been mistaken for those of grip. This illustrates the necessity of daily visits in doubtful cases, especially if there are smallpox patients in the neighborhood. The appearance of the eruption ought to correct the error. Syphilis has been mistaken for smallpox and the eruptions caused by the ingestion of certain drugs, such as cubebs, copaiba, and iodid of potash, may lead to a similar mistake. The absence of all febrile symptoms, the history of the patient, and the odor of the drug, will usually serve to correct the diagnosis.

Thrush in Nursing Infants.—HUTINEL (*Wien. Med Blat.*, August 17, 1899) says that an exclusive local treatment has only a palliative effect in cases of infantile thrush because the source of trouble is not local but is in the sour secretion of the mouth which is the result of an acid dyspepsia. His practice, therefore, is to wash out the stomach with an alkaline water, Vichy preferably, repeating the process twice daily. About six ounces of water are allowed to flow into the stomach and siphoned out again. In simple cases a cure is usually effected in three days. Even in severe cases it is rarely necessary to extend the treatment beyond six days. Local treatment of the mouth was altogether given up by Hutinel.

Calentura Compared with Yellow Fever.—TEBAULT (*New Orleans Med. & Surg. Jour.*, September, 1899) says that the specific fever existing in the tropics, to which the Spaniards have given the name of calentura, and which caused such a scare among the American troops after the surrender of Santiago, presents so many symptoms in common with yellow fever that a severe case of it may easily be confounded with yellow fever, especially if jaundice is present. In the majority of instances the fever is of two-and-a-half-days' duration and is preceded by a morning chill. The initial temperature (103° F. to 105° F.) is higher than that of yellow fever. The pulse becomes slow much sooner than in yellow fever and remains slow for a longer period. There is prolonged debility rather than "calm" or collapse. Gastric irritability is slight, jaundice less common, albumin absent or, if present only in small quantities. The liver is increased in size. There are no secondary infections. There is often bleeding at the nose but rarely hemorrhage elsewhere. Attacks are prone to recur every two or three months among foreigners and once or twice a year among natives. The fatality is practically nothing. The disease spreads more rapidly than yellow fever. Yellow fever often travels in the wake of the more active calentura or the two diseases may occur side by side; but yellow fever is so rare as compared with calentura that the writer speaks of it as a "four-leaf in a patch of clover."

THERAPEUTIC NOTES.

Calomel as a Diuretic in Cardiac Affections.—BOURGEON (*Rev. de Therapeut.*, August 15, 1899) says that diuresis produced by calomel in valvular affections of the heart increases as the drug is continued, but is essentially temporary in that its action ceases with the suppression of the remedy. The quantity of urine excreted is variable, and seems to depend upon several factors, such as the constitution of the patient, the nature of the trouble, and the degree of edema; but it is remarkable that polyuria is more accentuated when the dropsy is of cardiac origin. The daily quantity of urine voided ranges from a pint to three quarts, and the dose of calomel necessary to obtain diuretic effects varies from 3 to 6 grains per day. This amount should be given in one or two doses in a little milk every two, three, or five days according to circumstances. If albumin appears in the urine the calomel should be stopped. This powerful remedy should be reserved as a last measure. If digitalis, squill, milk-diet, and cooling drinks in large quantities do not produce diuresis, one may resort to calomel. As it is absolutely impossible to foresee its exact results it should be used with great caution.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, OCTOBER 21, 1899.

PHOTOTHERAPY AND ITS POSSIBILITIES.

During the past few years there have been occasional rumors of the possibility of the light-rays being used as a therapeutic agent, especially in skin diseases. It is well known that the violet rays of the spectrum affect bacterial growth unfavorably. Some years ago, Finsen of Copenhagen pointed out that the scars left after an eruption of smallpox, were much less serious if the patient were protected from the action of the rays of light belonging to the violet end of the spectrum, as these produce irritation of the skin when concentrated, and in inflammatory conditions such as smallpox naturally aid in the destruction of tissue and consequently intensify the subsequent pitting.

After demonstrating that his theory was correct and that the bad effect of these rays could be eliminated Professor Finsen experimented further with the idea of making use of the violet and related rays for therapeutic purposes. The results of his experiments were followed with great interest. Nearly two years ago Lesser, professor of venereal diseases and dermatology at the University of Berlin, in a lecture which appeared subsequently in the *International Clinics* said that the most promising therapeutic agent against lupus vulgaris, providing it proved as successful in other hands as in those of the discoverer, was Finsen's phototherapy. Finsen's demonstrations at the congress for tuberculosis in Paris last year did not come as a surprise but they did succeed in convincing the most skeptical of the important therapeutic power residing in rays of light.

Finsen's assistant, Dr. Valdemar Bie of Copenhagen describes in the *British Medical Journal* for September 30, 1899, the methods and results of Finsen's treatment. The only indications for treatment are that the disease be superficial, local, and of bacterial origin. So far the light treatment has been applied to lupus vulgaris, to lupus erythematosus, and to alopecia areata. In lupus vulgaris, as the pictures of patients before and after treatment attest, the result is probably better than that secured by any other method of treatment. The application is painless and the liability to relapse is slight. In lupus erythematosus the effect is not so satisfactory and relapses are rather frequent. In alopecia areata the results have been most encouraging and seem to demonstrate, beyond all doubt, that that affection is of bacterial origin.

The method of treatment consists in concentrating on the affected parts the violet and ultra violet rays of light. The sunlight of a bright day or the light of a strong electric-arc light of 50 to 80 amperes, is employed to furnish the white light. From this all rays except those chemically most active are filtered out by means of a blue lens. A hollow glass lens filled with a proper colored blue solution, as a dilute solution of ammoniated copper sulphate, helps to cool the rays as they pass through to the skin. For the electric arc, lenses of quartz are used because they allow the violet rays to pass more readily than do those of glass. The patients are protected from the heating effect of the concentrated light by a small hollow glass disk, pressed close against the skin, through which cool water is allowed to circulate constantly. A little experience soon gives facility in managing the apparatus and the danger of accident from the concentrated rays is very slight.

Professor Finsen's work deserves to be known and his suggestions to be put in practice on a much wider scale than has yet been attempted.

THE INCREASE OF CANCER REAL NOT APPARENT.

DIRECTLY after the publication of Dr. Roswell Park's striking article on the increase of cancer [MEDICAL NEWS, April 1, 1899], there followed quite a discussion in the medical journals of this country and of England as to whether the increase of cancer, according to the mortality statistics, was apparent or real. A number of letters were written by those who could not bring themselves to believe that cancer is really on the increase, in which they endeavored to show that the apparent increase is really due to better methods of diagnosis. A number of obscure internal conditions that were formerly set down in the mortality statistics under various names according to the special symptomatic condition that was most prominent in them are now correctly diagnosed and reported as cancer.

So great is the tendency to refuse to accept what is new, when it is a surprise or has been entirely unexpected, that the majority of the profession have been rather inclined to revert to this explanation of the statistical increase of cancer. It is undoubtedly true that the gradual evolution throughout the profession of better diagnostic methods as to internal cancer has led to the addition to the cancer mortality statistics of a certain number of deaths that were formerly set down as due to other causes, but this factor by no means is sufficient to account for the greatly increased prevalence of the affection that is reported from year to year.

The statistics of the Registrar-General of England for the year 1897 have become available since the discussion in the spring. Dr. Tatham in the introduction to the Registrar's report does not accept the view that the increase of cancer in recent years is only apparent, though he admits that during the decade from 1870 to 1880 this factor probably played an important rôle in the increased number of cancer cases reported. Since then the apparent increase for this reason has been growing steadily less and less, and at the present day we surely cannot say that from year to year there is such a progressive betterment of methods of diagnosis as would add markedly to the number of cancer cases reported.

In the London *Lancet* for September 16, 1899, Dr. Payne makes an interesting comparison between the death-rate from cancer and from tuberculosis in the female sex during the two years at the beginning and end of the last score of years for which we have reports. In 1877 the death-rate for females from cancer was 636 per 100,000, that from phthisis was 1967 per 100,000; *i.e.*, the cancer death-rate was less than one-third that of tuberculosis. In 1897 the death-rate from cancer was 929, that from phthisis 1162, per 100,000, a ratio of 4 to 5; that is, cancer now causes in English women four-fifths as many deaths as are caused by phthisis, a condition of affairs that is certainly very surprising especially to those who are prone to think of cancer as a comparatively rare disease.

Some of this approach of the death-rates from the two diseases is due to the improved methods of dealing with consumption which has made it much less fatal. The increment of nearly fifty per cent. in the death-rate per 100,000 from cancer is, however, sufficiently startling to make us realize the importance of the present comparison. This death-rate, it is to be remembered, is among women, while it has been argued that it was especially the statistics of cancer among men that showed that the increase was apparent not real. We are, then, surely in the presence of a highly increased mortality from cancer, and this is not due to the lessened number of deaths from infectious diseases, nor to longer average life, but to actual heightened incidence of the malignant affection.

MICROBES IN THE ARCTIC REGIONS.

RECENT explorers in both the Arctic and Antartic regions have brought back interesting information concerning bacterial life in the frigid zones. It has long been known that travelers in the Arctic territory suffer very little from excessive changes of temperature, and are entirely free from colds and coughs which are so frequently observed in the winter in our own latitude. Nordenskiold is authority for the statement that Spitzbergen in the summer time is the healthiest portion of the earth. Levin made a number of cultures of the air in Spitzbergen and in King Charlesland. Samples of air were taken on the surface of the glacier, on the coast, on the top of a cliff, as well as on board ship. In each instance at least 1800 liters (nearly 50 gallons) of air was filtered, indicating an elapsed time during the experiment of four or five hours. In only one in-

stance were bacilli found. In that case the air was taken from the deck of the vessel while it was in harbor, and as only three colonies of bacteria developed, it is at least a question whether a grain of dust from the ship did not get into the gelatin. On the other hand, all samples of water, whether taken from the surface of the sea or at a great depth, or from a glacier or obtained by melting snow or ice, were found to contain bacteria, although in very small numbers. At the surface of the sea Levin found one germ for each 11 c.c. (3 drams) of water—a quantity of germ-life which is absolutely insignificant. The same amount of water taken from the River Seine has been found to contain more than two million bacteria. A curious fact was noticed in that the water taken from the ocean at great depth invariably contained more bacteria than water from the surface, and this in spite of the fact that deep water in the Arctic Ocean is usually below the freezing-point. Levin made another series of experiments in order to determine the bacterial condition of the intestinal contents of various animals, white bears, seals, reindeer, eider ducks, penguins, gulls, frigate birds, sea-urchins, sea-anemones, shrimps, etc. These experiments showed him that in most of these animals the contents of the intestine are almost entirely sterile. In one white bear and in two seals was found a species of bacteria which resembled the bacillus coli commune. The inferior animals, sea-urchins, sea-anemones, etc., usually contained bacteria.

While scientists have long held that bacteria are not indispensable to digestion, it is extremely interesting to receive this proof of their statement direct from the natural world. This fact and the fact of the existence of a whole world of bacterial life at a temperature sometimes 3½° F. below the freezing-point are the most valuable results of Levin's researches, a full report of which will be found in the July number of the *Annales de l'Institut Pasteur*.

THE PLAGUE ONCE MORE.

We stated recently that just when the sanitary authorities at Alexandria were sure that they had seen the last of the plague, and just after the editor of the *British Medical Journal* had thought it opportune to compliment them on their happy deliverance from the dread disease on such comparatively easy terms, came the announcement of the discovery of new cases of bubonic plague in the city, some of which proved fatal. Almost the same thing has happened at Oporto in Portugal. At first every assurance was given that the disease would be kept well under control. Successive official reports were more and more encouraging until it looked as if all danger from this quarter could be considered as past. Then came disquieting reports as to the doubtful efficiency of the sanitary cordon that had been established. Finally, there are definite accounts of a recrudescence of the disease in Oporto and its occurrence among the soldiers who form the military cordon of sanitation.

We have pointed out before that this intermittent method so well calculated to disarm suspicion is not new to the plague, that it has been in fact characteristic of its invasion in all the great epidemics of history. By the people in Portugal the danger from the plague has never been taken seriously. On the contrary, they oppose in every way the enforcement of the sanitary regulations necessary to prevent its spread. Only last week there was the report of plague quarantine officers while on duty having been stoned by the people and compelled to call upon the military for protection. Even intelligent people insist that though the disease is present it will not spread in epidemic form in the present condition of civilized life.

This attitude of overconfidence in the safeguards of modern life was what gave plague its hold in India during the present epidemic, and it is constantly spreading there now despite all that is being done. These recent failures to stamp out the disease at Alexandria and Oporto show that it is not so easy to deal with as was thought. They emphasize the necessity for the strictest quarantine regulations to prevent its entrance. We have previously pointed out our danger on the Western coast and the necessity for constant watchfulness. In the light of recent events especially the occurrence of chronic ambulant cases of plague, another source of danger becomes manifest. There is the possibility of plague gaining an entrance at some of our lesser ports where only sailing vessels touch. At these points medical officers are apt to be unfamiliar with plague and vessels may more readily escape rigid in-

spection. The present prosperous trade conditions have made the possibilities for plague invasion by this way even greater than before. No precaution should be spared to make these lesser ports as secure as those of the large cities, for a Nation's quarantine is only as effective as its weakest point.

ECHOES AND NEWS.

The Tri-State Medical Society.—This society, which covers in its scope the States of Alabama, Georgia, and Tennessee, will hold its eleventh annual meeting at Chattanooga, October 24, 25, and 26, 1899. The preliminary program has already been published.

A Paris Doctor of Pharmacy.—The degree of Doctor of Pharmacy has just been conferred by the University of Paris for the first time. The recipient is M. Lacourt, who presented a graduation thesis, entitled "Historical, Chemical, and Bacteriological Study of the Versailles Water."

Obituary.—Dr. J. N. Brownlow of Ogdensburg, New York, died suddenly of angina pectoris on October 10th, just after he had delivered an address before the Northern New York Medical Association. The doctor was sixty-five years old.—Assistant-Surgeon W. R. McAdam, who was in charge of the Marine Hospital at Key West, died of yellow fever on October 12th.

Physician Robbed in Chicago.—Dr. Oscar W. Hubbard, a Chicago physician, was waylaid by two highwaymen on the morning of October 14th, just after he had visited a patient. Revolvers were pressed to his head, he was dragged into an alley, thrown to the ground, and robbed of a gold watch and diamond pin. One of the robbers was caught and identified by Dr. Hubbard.

The American Public Health Association.—The twenty-seventh annual meeting of this organization will be held at Minneapolis, Minn., October 31 and November 1, 2, and 3, 1899. The topics for discussion, as announced in the program, quite completely cover the entire field of hygiene and sanitation. Railroad and hotel accommodations have been arranged for and a large and interesting meeting is expected.

Death from Hydrophobia.—Charles O. Young, a boy seven years old, living in Jersey City, New Jersey, was bitten on the hand by a vagrant dog about six weeks ago. Two physicians made a diagnosis of acute hydrophobia. Dr. Gibier was consulted on October 11th. He advised that the time had passed for the possibility of effective treatment by the Pasteur method and that the Bouisson hot-vapor treatment be tried. This was ineffectual and the boy died in great agony on October 13th.

California Not to Bar Consumptives.—The State Board of Health has decided not to quarantine California against the consumptives of other States. It has adopted a resolution, however, recommending that in all State institutions those afflicted with tuberculosis be separated from the other inmates. This is a very sensible modification of the radical measures of absolute exclusion of all consumptives at first proposed. While tuberculosis is undoubtedly contagious it is not so to such a degree as to make quarantine regulations advisable.

The Influence of Americans in Cuba.—*El Epoca* of Havana says: "Contact with a race which does not tolerate the shirking of daily labor, and among which, before everything, a man is the legitimate child of his own merits and his own deeds must be to us a powerful stimulant for discarding once and forever the accumulation of habits which constitute the unfortunate inheritance of a régime based upon the exploitation of the negro by the white, and the native born white by the peninsular white, and all by the government."

The Loomis Sanitarium Burned.—The Loomis Memorial, or Administration Building, a gift of Mr. J. Pierpont Morgan to the Loomis Sanitarium at Liberty, Sullivan County, New York, was entirely destroyed by fire on October 14th. The loss is from $75,000 to $100,000; the insurance is $50,000. There were one hundred inmates, all of whom were removed safely. The nine surrounding cottages and the other buildings remain intact. The fire is supposed to have originated from the explosion of an alcohol lamp.

Some Enormous Tumors.—The *Lancet* has lately presented some remarkable records of tumors. The largest known uterine tumor weighed 195 pounds, described by a Bucharest physician. Hunter of New York removed one weighing 140 pounds from a woman whose weight without the tumor was 95 pounds. The largest fibroid is said to have weighed 106 pounds. The record for ovarian tumors is held by a Chinese patient, who had one weighing 169 pounds; without it she weighed 77 pounds. For mammary tumors a case is recorded in which the growth in one breast weighed 46 pounds and in the other 40 pounds.

The Yellow-Fever Situation does not show much change from last week. There was one death from the disease at New Orleans on Friday of last week, but recently no new cases have been reported. It is announced that Spain has quarantined against New Orleans because of the presence of yellow fever, and it is thought that other Mediterranean ports will do likewise. This seems an unfortunate and needless precaution, now that the epidemic is practically over. New cases of yellow fever to the number of about 15 or more are being reported every 24 hours at Key West. Santiago de Cuba had been remarkably free from yellow fever for some time until the disease was imported from Havana.

Our Troops in Cuba Healthy.—In a letter which Surgeon-General Sternberg received on October 9th from Major Vallery Harvard, Chief Surgeon of the Department of Santiago and Puerto Principe, it is stated that the percentage of sick men in the commands with which he is

connected seldom exceeds five per cent., practically all the sickness being malarial fever of a mild type. At Puerto Principe nearly two regiments are in camps, having been driven from their barracks in the city by yellow fever. These are model camps as regards hygiene and comfort, and the sickness in them is only four per cent., just about the same as in the United States. Our troops cannot safely live in the Cuban towns. With the exception of those at Baracoa, Gibara, and Holquin, which have not yet given any sign of infection, all the old Spanish barracks in the towns have been abandoned.

Indian-Plague Horrors.—A correspondent of the *Scotsman* writes concerning the plague in the city and cantonments of Poona, that to Defoe's most realistic pictures of the plague of London must be added the Asiatic peculiarities. There is the funereal pyre of the Hindu for ghastly cremation, deserted the moment it is lit, and then abandoned to the jackals and the vultures. There is the ghoulish Mohammedan cemetery, where the bodies are tossed or dragged, and not one foot of earth covers them. So few of the living are left to remove the dead that, as in London, the death-cart goes its rounds and disposes of the victims wholesale. Two-thirds of the city's native population have died or fled, and among the remaining third there are 1100 deaths a week. Two new features which have lately appeared are the black death and the fatal infection of Europeans. The latter is chiefly due to the impossibility of nurses and physicians and benevolent persons dealing with the hundreds who crowd the hospitals, "and yet they must work on till they themselves drop." Since August 1st 500 victims a day have filled the General Plague Hospital, notwithstanding the fact that only 104 have been returned as cured in the first fortnight.

The New York State Medical Association.—The program of the sixteenth annual meeting of this society, to be held October 24, 25, and 26, 1899, at the New York Academy of Medicine, New York City, has been issued. It gives promise of an unusually interesting occasion. The important feature of the meeting will be the discussion, to be held Tuesday evening, October 24th, on "Medical Expert Testimony." The speakers will be Hon. Willard Bartlett, Justice of the Supreme Court; Hon. Joseph F. Daly, former Justice of the Supreme Court; Charlton T. Lewis, Esq.; William A. Purrington, Esq.; and Theron A. Wales, M.D. A discussion on "Typhoid Fever" will take place on the afternoon of Wednesday, October 25th. Papers will be read on this subject by Drs. Herman M. Biggs, W. H. Park, Wm. Osler (of Baltimore), W. H. Thomson, Reginald Fitz (of Boston), A. A. Smith, Abram Jacobi, De Lancey Rochester (of Erie County), W. W. Keen (of Philadelphia) and A. T. Hubbell (of Erie County). The individual papers on various subjects will discuss topics of practical interest. On Wednesday evening, at the Academy of Medicine, a reception will be given to the invited guests of the society, Professors W. W. Keen, William Osler, and Reginald H. Fitz. Special invitations have been sent out for this occasion.

The Status of Therapeutics in France.—A correspondent of the *Boston Medical and Surgical Journal*, in a letter on this subject, paints a doleful picture of the decline of therapeutic knowledge in the rising generation of French doctors. Quoting a professor of materia medica he says: "It must be admitted that the scandal of our times is the shameful ignorance shown by an infinite number of physicians concerning the real action of drugs. Although our practitioners are pretty fair clinicians, they are almost all unaware of the true properties of the remedies which they handle every day with extraordinary heedlessness." It is admitted, however, that this is due to the skeptical attitude on the subject of drugs entertained by the professors themselves. One is quoted as saying in a lecture: "Gentlemen, when you are in practice you will see that the point that will most impress a confrère is a correct diagnosis; the patient's family will be most impressed if your prognosis turns out correctly; but you yourself will be most impressed when your treatment is followed by any improvement that you think can fairly be ascribed to it." The young doctor, therefore, when he comes to start in practice, is obliged to resort to one of two expedients: he either hurriedly learns by heart a certain number of prescriptions from some of the many books of formularies, or else he prescribes proprietary medicines. How rapidly is the profession of America drifting in the same direction?

A Case of Cerebrospinal Rhinorrhea.—Dr. St. Clair Thomson of London presented recently before the London Laryngological Society a case in which he succeeded in demonstrating to the satisfaction of his brother specialists that the practically continuous rhinorrhea was really a discharge of subarachnoidal fluid. The discharge, except for the annoyance of its continual dropping, did not inconvenience the patient in the least. On the contrary, vague pains in the head from which the woman suffered before the establishment of the discharge have since ceased, and only return when for some reason there is a temporary obstruction to the flow. Dr. Thomson has succeeded in finding in medical literature reports of some twenty cases, which he thinks should be classified in the same category with the one he has had under observation. Most of them have been described simply as persistent "dropping of watery fluid from the nose." Beyond the fact that this is an actual cerebrospinal rhinorrhea, very little is known. Dr. Thomson himself thinks that it is probable that the fluid finds its way from the subarachnoid space at the base of the skull, within the perineural sheaths of the branches of the olfactory nerves, though of course the possibility of its finding its way by some other route cannot be denied. He thinks that the condition is always associated with increased intracerebral pressure. Of the twenty-one patients, including his own, no less than seventeen presented some cerebral symptoms, and eight of them showed retinal changes.

The Mosquito as a Disseminator of Malaria.—Of great interest was the paper by Professor Grassi of Rome, presented at the meeting of the German Naturalists and Physicians, recently held at Munich, concerning the inoculation of malaria through the study of

the *anopheles*. According to Grassi, Koch has simply repeated the investigations and confirmed the results of Ross and Bögeln, and has made no direct experiments on man. Such, however, were made by Grassi and his co-workers, Bignani, Bartianelli, and Dionissi, in the damp, feverish surroundings of Rome, and through study of the zoological side of the question very weighty results were obtained. Grassi differentiated three species of parasites found in the red blood-corpuscles, namely, hæmameba malaria, vivax and precox. In all three species, which by many are looked upon as one, an asexual multiplication takes place in the blood of man, and finally so-called half-moon forms, with flagellæ, are seen. As in other protozoa, so also in the malarial parasite sexual multiplication finally occurs. This takes place in the blood after its ingestion by the mosquito. The flagellated crescents are the spermatoids and other larger bodies, the ovoids. In the mosquito fertilization follows, while in man the forms remain sterile. From this union there is found in the intestine of the mosquito a gregarinaceous stage, in which the young sporozoa develop. These finally become freed, are absorbed, and find their way to the salivary glands, so that when the mosquito stings they are injected into man, and the cycle is again completed. This occurs only with the mosquito known as *anopheles*, and not, as Koch believes, in the *apicus culex*, since experiments with the latter have always given negative results. For the development usually a temperature not less than 16° C. is required, and better 20° or more, which is found in the mosquito. From January to May the forms are absent in the mosquito.

The Plague Situation has not improved. Fresh cases of plague continue to occur at Oporto in Portugal. Soldiers engaged in duty with the military cordon have developed plague. Moreover, outside the military cordon, 10 cases and 5 deaths have occurred at two villages. In consequence of these outbreaks the cordon of troops has been extended. This is the old story : the cordon serves but to spread the disease, and is a form of quarantine which ought to be discredited and forbidden. During September there were 17 cases of plague altogether in Oporto and 4 deaths from the disease. There is no news of plague in any other part of the Peninsula. There are certain persistent rumors that cases have occurred and are occurring in France, but they seem no more than the merest rumors. France has wakened to the danger on her Mediterranean coast. On her northern coast, too, special precautions are being taken. The *British Medical Journal* for October 7, 1899, says : "The plague epidemic at Oporto continues to cause anxiety to the French Government. All along the coast, from Brest to Hendaye, warnings have been issued to the fishermen to refrain from visiting the northern ports of Spain and Portugal, whither they are accustomed to go in search of bait. Not a single death has occurred among the patients who were inoculated with the serum from the Pasteur Institute, and Dr. Metchnikoff declares that France need have no fear of an epidemic, and that it was only due to the stupidity of the Portuguese authorities that the epidemic was continuing to prevail. On October 14th, a case of plague was discovered at Plymouth, England, on board a vessel which had just arrived from Bombay."

At Alexandria a repetition of the usual game of hide and seek on the part of the plague has occurred again. The city was officially reported free of plague in September when, on the 23d of that month two new cases occurred. Once more the absolute banishment of the disease was announced, but last week, at least one fresh case appeared. The situation in India is decidedly improved and would look very hopeful but for the fact that among the new cases being reported each day there is usually one or more among the white population. They have up to this time, been reasonably immune to the disease, but the epidemic has evidently acquired sufficient virulence to overcome this immunity. The *British Medical Journal* in the last issue that reached us sums up the state affairs in India as follows : "During the second week in September the total plague mortality amounted to 4094 in the Bombay presidency alone, and of these well-nigh one-fifth occurred in the city of Poona. In Calcutta during the period referred to 45 deaths occurred. In Poona the virulence of the epidemic is expended and the city is beginning to resume its normal appearance. Several officers of the Royal Scots Regiment have suffered from plague in Poona." The disease has subsided at least temporarily on the Chinese coast. At Mauritius it still rages severely. During the last week in September 55 fresh cases and 47 deaths occurred on the Island. At the beginning of October it was raging with the same virulence.

MEDICAL MATTERS IN NEW YORK.

DEATH OF DR. JIMINEZ—SMALLPOX IN A BATTERY TENEMENT—A FRAUDULANT SOLICITOR FOR HOSPITAL FUNDS—MEDICAL "SCHOOL INSPECTION"—CITY AID FOR PRIVATE CHARITIES.

DR. PEDRO Y. JIMINEZ, a Puerto Rican of noble birth, who until recently was a house surgeon at the Columbus Hospital in this city, died on October 7th. He was a Bellevue graduate.

A Syrian immigrant, who had come from Europe only a week before his death, died from smallpox on North Brother's Island October 9th. He had been living in a Battery tenement with some 300 other people, and the inmates are being carefully watched for the occurrence of additional cases of the disease.

A sleek-looking individual in clerical garb has been soliciting contributions for the German Hospital and Dispensary. This hospital does not employ any person to solicit subscriptions, and it is hoped this swindler will be apprehended and jailed.

Dr. Henry G. McAdam read a paper before the City (Charity) Hospital Alumni recently on "The Benefits of Medical Public School Inspection." This movement was begun under President Wilson of the Health Board of New York City in 1897. During the first three months of the inspection 2637 children suffering from contagious diseases were excluded from school. In 1898 the average total attendance per day was 456,394. There were re-

ferred for examination 139.965 children, of whom 7606 were excluded, with the following distribution:

Parasitic diseases of the head	3502
Contagious eye diseases	1627
Skin diseases	703
Mumps	517
Chicken-pox	380
Whooping-cough	276
Measles	253
Parasitic diseases of the body	152
Diphtheria	118
Scarlet fever	32
Croup	25
Miscellaneous	21
Total	7606

It has been no uncommon thing in the past to see public schools closed because of epidemics among the children; under the present system this has already become an impossibility. The value of this inspection as regards the suppression of contagious diseases throughout the city generally, though it cannot be measured, is no doubt very great.

Representatives of many private charitable institutions were present at the meeting of the Board of Estimate on October 13th, when the final items in the city budget for 1900 were considered. A synopsis of the suggestions made by Comptroller Coler in his report of September 1st, and of the resolution which he offered in connection with the report, were read, and the representatives of the institutions interested were asked to express their opinions. Nearly all spoke in favor of the recommendations. Only Henry W. Maxwell of the Long Island College Hospital and Mrs. E. V. V. Knox of the American Female Guardian Society spoke in opposition to them. The Comptroller's plans were modified at the suggestion of the Mayor, so that as read, they excluded the apportionment of all public money for private charities from the budget, but not from the Excise Tax Fund, the Concert License Fund, and the School Fund; that all institutions caring for children receive aid at the rate of $2 a week for each child; that hospitals receive aid at the rate of $1 a day for surgical, and 70 cents a day for medical patients; that no out-door relief be aided; that aid to various miscellaneous charities be cut down one-half next year and stopped thereafter; that separate accounts of disbursements of money received from public and private sources be kept; that payment be made only for the care of persons accepted by the Department of Charities as a public charge; that the institutions receiving aid be open to inspection; and that the Comptroller be empowered to recommend to the Board of Estimate the stoppage of aid to any particular institution whenever the public interest demands it.

Isaac Stern, Vice-President of Mount Sinai Hospital, informed the Board that his institution asks for the same amount for next year as it received this. When asked if he had any objections to the Comptroller's suggestions he answered: "Not at all. By the Comptroller's plan we would get 70 cents a day. At present we get 40 cents a day." At this the Mayor opened his eyes, and he wondered why 40 cents was not sufficient.

The Comptroller also offered a resolution, to which the Board assented, by which the accounts of all charitable institutions receiving public moneys shall hereafter be so kept as to show the receipts and expenditures of public moneys separately from the other funds of such institutions, and that all institutions shall keep an exact record, to be corrected from time to time, in a form to be approved by the Comptroller, showing the addresses of the parents, guardians, or nearest relatives of inmates, and other information designed to facilitate inquiry into their financial ability to provide for such inmates.

CORRESPONDENCE.

PUERTO RICO IN TIMES OF PEACE.

[From a Special Correspondent.]

YABUCOA AFTER THE HURRICANE—REVOLTING CONDITION OF THE INJURED—PLUCK AND PERSEVERENCE OF AN AMERICAN MEDICAL MAN—SHIFTLESSNESS OF THE NATIVE PEURTO RICANS.

San Juan, Peurto Rico, October 5, 1899.

It may probably be of interest to give a few particulars of an experience I have had recently in the district of Yabucoa, Peurto Rico. It will be remembered that this section felt the full force of the hurricane, and that Yabucoa was the only town on the island that was totally obliterated; therefore, the need for help was urgent, especially in the line of medical assistance.

Responding to an appeal from the Board of Charities for medical volunteers, a few days after the storm I found myself where the town had been. One building alone, a church, was standing, and it had been turned into a hospital for the large number of wounded. It must be borne in mind that this so-called hospital was merely a shelter, and an imperfect one at that, every door having been carried away, and part of the roof badly damaged. I found the following horrible condition of things: More than ninety wounded men, women, and children were lying promiscuously on the stone floor. No attempt had been made to separate the sexes, and there was absolutely no provision for the relief of natural wants As there was practically no medical attendance, and actually no medical supplies, the wounds were almost universally in a condition that no young medical man is ever likely to have seen. Fancy the state of the floor as a result of scores of sloughing, stinking wounds, and the solid and liquid evacuations of a hundred people!

It was enough to discourage a man, but something had to be done and that quickly. First I separated the sexes, and made some kind of provision for sanitary needs, and had thorough cleansing and disinfection of the floor carried out. Next in order came the work of examining and diagnosing the injuries, most of which were severe, and many of the most ghastly description. The scalp wounds were unusually horrible, as no suturing had been done, and every wound was widely gaping, often to the extent of several inches. Compound factures of the leg and arm were very numerous, and of these some were of such a nature that amputation was the only resort. There were examples of almost every conceivable surgical injury to be

found in the crowd, and for the moment I almost despaired of being able to do anything of consequence with the limited appliances at my disposal. However, I made the best of it; turned the organ gallery into an operating-room, the space inside the altar-rails into a dressing-room for those able to walk, and the altar itself was converted into a table for the bandages and the other surgical appliances. With the aid of two or three volunteer assistants every wound was thoroughly irrigated with bichlorid-of-mercury solution, and dressed with carbolized and borated ointment. Such wounds as were suitable were sutured, and others fixed with adhesive plaster and bandages. Splints were improvised from various materials, and all factures properly set, to the immense relief of the unfortunate patients.

Although I had gone to Yabucoa solely with the intention of offering my services to the local medical men, I found myself unexpectedly placed in the position of surgeon to a military hospital, and at once determined to run the concern on purely military lines. My former army experience made this easy, and in less than a week the hospital was one in reality, and running like clockwork. A kitchen was extemporized from some of the débris, closets were built for men and women, and the feeding of the patients carried out on business lines. The most rigid discipline was necessary, and was strictly enforced, for otherwise any decency or order would have been impossible. Fortunately I was allowed a free hand by the local authorities, and my word was law. For the first few days the work was cruelly severe, but I afterward obtained the help of two Hospital Corps men, and my burden was greatly lessened. Of course antiseptic surgery as commonly understood was impossible, and we could only trust to the greatest possible cleanliness as a substitute; but in spite of the imperfect asepsis and the abominable filth of the patients and of their clothing, the results were really remarkable, and healing progressed in every case almost as rapidly as if the environments were ideally perfect. Only two deaths occurred from wounds after I took charge, one being in a case of secondary amputation of the thigh in a young woman five-months' pregnant. She did well for ten days when she miscarried and died the next day in convulsions. The other case was that of a young man whose knee-joint was literally smashed to atoms and who was dying of septic fever when I first saw him.

Even the worst cases of compound fracture did well under the simplest treatment, and I attribute much of the remarkable result to the fact that the patients were living practically in the open air. Besides this, they were receiving more and better food than they ever had in their lives, and to this fact great weight attaches. Rice, beans, and coffee comprised the bill of fare for the great majority, milk, eggs, etc., being issued to a few special patients. A quantity of different foods was sent me, but, strange to say, none of the patients would touch any of them. Oatmeal, Boston beans, corned beef, canned tomatoes etc., were valueless in their eyes, and I had to trade these off in the town for coffee or other suitable articles. I may call attention to two striking features in the character of the Puerto Rican of the poor class: one is the absolute indifference to the suffering of others; the other is a total absence of a sense of decency or modesty. Nothing but the utmost severity enabled me to keep under control their bestial impulses, but one or two public examples gave them to understand that they had at least to conform to civilized ideas. On the whole the character of the Puerto Rican is a singularly unlovely one, and any one expecting to find in them the sweet and gentle traits so persistently attributed to them by well-meaning people who don't know them will very quickly be disillusioned. The lower classes are universally immoral, or rather unmoral, are indescribably lazy, and will steal anything not too heavy to lift. Even my instruments were not sacred in the eyes of the people in whose service they were used, and I lost a number of them. Rations were stolen at every point, and to such an extent had laziness been cultivated by the lavish food distribution that it was impossible to get any work done even for fair wages. The ladies of Yabucoa had to do their own washing, as the laundresses were perfectly content to live in idleness at Uncle Sam's expense just as long as he did not object. Every intelligent man is delighted at the prospect of an early stoppage of rations in the sugar district, for he well knows that there is not the most remote chance of any one dying from starvation except as a suicide. In the coffee districts relief may be required for some time to come, but in districts like Yabucoa and Maunabo the need for relief has happily passed away.

In conclusion I wish to express my hearty thanks to Colonel J. V. R. Hogg, U. S. A., President of the Board of Charities for the prompt and liberal way in which he answered my demands on him. Also to Captain E. Swift, commanding officer of the district, and to Assistant Surgeon Russell, U. S. A., for every moral and material assistance that could be afforded. But for such aid my work would have been a failure, and I am anxious that a full share of the credit should be given where it belongs.

W. F. SMITH, M.D.

OUR LONDON LETTER.

[From Our Special Correspondent.]

OPENING OF MEDICAL SCHOOLS—OPIUM IN THE ENGLISH FENS—POST-MORTEM REVELATIONS OF SYPHILIS—IMAGINATION IN MEDICINE AND IN MARQUISES—SANITARY SCANDALS AMONG HOP-PICKERS—SNAP DIAGNOSIS OF BULBAR PARALYSIS—SELF-POISONING BY A DOCTOR—HEREDITY AND DRUNKENNESS—ALLEGED "BRUTALITY" OF DR. LAMONT TOWARD THE BODY OF A PAUPER—BARBAROUS COWARDICE IN SOUTH UIST EPIDEMIC.

LONDON, October 8, 1899.

WITH the opening of the great hospital medical schools last week the London medical "season" began. With a depressing lack of originality, all of them opened at the same hour of the same day, and on a Monday at that. Instead of avoiding the first day of the working-week as a point of departure, as has become, for obvious reasons of convenience, the unwritten law of all our American medical colleges, they seem positively to pre-

fer it. The smallness of the country and shortness of the average railway journey may have something to do with it, but the iron hand of custom has probably more. It's a sort of inheritance from boyhood's hour, and the tradition of the boarding-school which invariably began on "Blue Monday."

Nearly all of the schools usher in the year with a solemn Address, delivered by some celebrity, if possible from their own alumni, and several of them have the curious habit of holding their annual Dinner (this word is always to be spelled with a capital D in public, in England) the evening following this cheerful ceremony, just such a "class reunion" as we hold at the other end of the year. Every medical school (a "college" in the insular tongue is an examining body) in London is an appendage to a hospital instead of the hospital being an appendage to the school, as it should be. Practically, no one can become a teacher in any of the schools, except in the purely scientific branches in some cases, without first getting on the staff of the hospital, so that the choice of lecturers and teachers is largely controlled by the lay governors of the hospital, many of whom are not merely ignorant of the needs of medical teaching but even unfriendly to its interests.

A curious item has been going the rounds of the London papers in regard to the opium habit in England. It is alleged that in several of the rural districts the regular use of opium in moderate doses is not uncommon. Certain it is that it is the favorite article chosen by Oriental sailors for smuggling into London. The region most addicted to its use is said to be the fen district of Lincolnshire and Cambridge. And this may have a distinct pathological basis, inasmuch as this region was the last in England to get rid of ague by the draining of its famous fens, or huge swampy levels, and opium is esteemed highly the world over by the native populations as a prophylactic against malaria.

A case illustrating both the worthlessness of even utterly negative evidence in conditions of suspected syphilitic origin, and also the dramatic way in which medical "murder" like the other variety "will out" was related by Mr. Jonathan Hutchinson at his last clinical demonstration at the Polyclinic. A number of years ago he was consulted by an intelligent farmer for an attack of ophthalmoplegia externa. The case was an extremely severe one, every trace of contractile power in all the recti muscles being lost so that the eyes were as immovably fixed as those of a graven image. The usual syphilitic origin was suspected, but the patient absolutely denied it, and the most searching inquiry and examinations failed to discover a shred of evidence of venereal disease. The man was even asked to bring his children up for examination, and brought with him two fine, well-grown healthy lads, without a trace of hereditary taint, so that Mr. Hutchinson finally believed his statements and had to confess that ophthalmoplegia externa was sometimes of non-specific origin. A year or two later the patient died, and a post-mortem was secured, but nothing was found to throw any further light on the question of causation. Several years passed and the lecturer had almost forgotten the case when one day a physician in the north of London wrote to him saying that he had just seen the daughter of this farmer professionally, and as she seemed to present distinct suggestions of hereditary syphilis, he, remembering Mr. Hutchinson's interest in her father's case, thought he might like to see her. Upon examination she was found to present a typical picture of inherited disease, in teeth, lips, and nose, and her threatened eye-trouble developed into a severe attack of interstitial keratitis.

It turned out that the unfortunate girl was the first-born of the family, and several years older than the boys seen by Mr. Hutchinson, during which interval the disease had apparently run its course past the infective stage.

England is having a perfect plethora of sanitary congresses. The echoes of the national gathering at Southampton have scarcely died away, and now there has been another in session, the Royal Institute of Public Health, at Blackpool, near Liverpool. This was opened by no less than a son-in-law and "poorer half" of royalty, the Marquis of Lorne, husband of the Princess Louise and the late Governor-General of Canada. His speech was a marvel of ingenious credulity, as might have been expected of a son of the Duke of Argyll. He took for his subject the influence of the imagination in disease and drew on his own liberally.

The wireless electric current has at last explained telepathy, thought transference, "absent treatment," etc., and ere long perchance the "directing will" of the physician will be all that is needed, and his actual appearance at the bedside no longer required, except perhaps in surgical cases, and even here healing might be hastened and antisepsis aided, by inducing such thoughts as would support the body and lead to recovery! Fancy thought as an antiseptic! Some of it is sterile enough, in all conscience, but we had never thought of it as a germicide!

Not only are the modern "mysteries" of thought-healing, etc., to be explained by wireless telegraphy—how the good Lord—Lorne only knows — but the marvels of the Ancients, also, Egyptian magic in particular. "What," asks our Marquis dramatically, "was the secret of Egyptian magic?" The same old secret, that of the priests in all ages, how to fool the people and get a fat living out of the process. Some delighted idiot is sure to hail each new discovery "electricity," Röntgen-rays, Marconi current, as "explaining" something that never happened or demonstrating the truth of some exploded humbug.

It is alleged that if the plague were to gain a footing in England there is one place on the Island where it would find itself thoroughly at home and in surroundings as superbly filthy as the houses of the Middle Ages, and this is the part of Kent now inhabited by the dense swarms of hop-pickers from the London slums. Many of these camp in wretched hovels, unlighted save by the door, with no furniture and nothing but straw on the earth floor to sleep on. As the dens are only used for a few weeks once a year the farmers will not trouble to provide anything better, and such is the crowding that from six to ten of the pickers will sleep in a cubby-hole not more than

ten feet square. And the straw, like the rushes of the Middle Ages, is made to cover all sorts of offal and excreta. To tolerate this state of affairs is a disgrace to England's sanitary reputation.

A new diagnostic symptom of bulbar paralysis is credited to Dr. Hughlings Jackson: "If the patient comes into the room with a slate in one hand and a large pocket handkerchief in the other, then you may diagnose bulbar paralysis at sight," and the touch is a most graphic one, for usually, all these unfortunates as soon as the disease is well advanced are obliged to use a slate for conversation purposes on account of the involvement of the laryngeal muscles, and a handkerchief constantly to soak up the steady drip of saliva from their hanging lips.

The late Inebriates Act, which was regarded as such a long step in advance, and for which the late Dr. Norman Kerr and many other medical advocates of temperance reform worked so hard, is proving a dead letter. And this by a most senseless failure on the part of the government or rather a succession of them. The Act authorizes magistrates and judges to commit habitual drunkards to reformatory institutions for a term of years. As first drawn it contained no provision for either the expense of the prosecutions or the support of the inebriate while in the reformatory. This was remedied at the next session of Parliament, but no provision made for building reformatories, only permission given to utilize those already existing. As those "already existing" prove on investigation to have room for barely one-fifth of those convicted so far, the Act is simply "hung up," and the magistrates are refusing to commit under it.

A most singular and tragic fatality has recently occurred in the profession here. A young physician at Eastbourne, Dr. John Dick, was fatally poisoned with a dose of his own medicine. It is proverbially unsafe to compound one's own prescriptions, but seldom is it followed by such bad results. The doctor was consulted by a patient, and deciding that she needed a tonic, he prepared and sent her a bottle of medicine. Next morning the patient took a dose of the mixture, and such severe cramping pains followed that she became alarmed and called in another physician. Later in the day Dr. Dick called at her house and she told him what had happened. Not unnaturally annoyed he declared that it certainly could not have been the medicine, and to prove it he would take some of it himself. This he did and in a few minutes repeated the dose. But before he could reach his house, a mile away, he was in strychnin convulsions, and though with great coolness and courage he called for his own stomach-pump and emptied his stomach, in spite of this and the utmost efforts of three of his colleagues, he died in a few hours. The tonic was found to contain a large amount of strychnin, which the unfortunate young fellow had probably put in, in mistake for some other white powder, or by one of those curious fits of absentmindedness to which all are liable added to the mixture twice or three times instead of once. The only moral appears to be, "don't dispense your own medicines, or if you do never use your strychnin in powder form but always in solution." The wonder is that so few accidents of this sort happen.

Dr. Archdall Reid has done a real service by his recent paper on "Alcoholism and Heredity," in calling the attention of the profession to the undoubted but often ignored fact that nations do not tend to become more drunken as time goes by but rather the contrary. Nearly all the nations of antiquity were at one time intemperate as their records show, and then became extremely moderate in the use of alcohol, as for instance, the Jews and the Egyptians are at the present day. All modern nations which have had the vine for long periods are now sober and even abstemious, as the Spaniards, the Italians, and the Southern French. Only we recent barbarians of the North who have had plenty of liquor for hardly five hundred years are now drunken. And we too in time shall become temperate, and useless, like the rest. Drunkenness is not inherited, first, because it is an acquired character, and second, because it is an unfavorable variation which tends to promote the elimination of those in whom it occurs.

The more the *cause celebre* of Dr. Lamont is looked into the more astonishing it becomes. It will be remembered that some months ago he as parish-doctor of South Uist, on the West Coast of Scotland, was suddenly arrested upon the flimsy charge of having issued vaccination certificates to children whose arms showed imperfect scars, kept in jail two or three days and dismissed in disgrace from his position, all by the Parish Council. So outrageous was the injustice of their course that the matter was actually brought before Parliament which passed a scathing vote of censure and promised substantial compensation to Dr. Lamont. Thereupon the Council suddenly changed its ground and announced that he had been dismissed on account of brutal and revolting treatment of the body of a pauper in preparing it for burial, dragging it out of the house by a rope tied to one leg, thrusting it naked into its coffin, and inflicting other indignities. This seemed so incredible that one's first thought was that the Parish Council had gone crazy, but now comes the report of the investigation committee of the Local Government Board and turns the tables with a vengeance. The body in question was that of an old woman who died in an epidemic of typhoid which had so terrified the cowardly natives that neither health officer, nurse, or relatives could be induced to go near many of the victims in their last days, and Dr. Lamont had been obliged to play the superhuman rôle of *physician, nurse, and undertaker to all of them.* It was the public and shameful rebuke which he had thus given the cowardice and inhumanity of the islanders and their officials which got into the papers and brought down upon them the severe rebuke of the Local Government Board that was the real cause of the reckless rancor with which the Parish Council had pursued him.

There was bitter truth in their description of the terrible coffining scene, but it did not cut Dr. Lamont. The fact simply was that out of fifty or more people assembled not one could be induced to go within fifty yards of the house, except the joiner who had made the coffin, and who had refused to touch the body, so that as the corpse was a

heavy one, the only thing Dr. Lamont could do was to convey the coffin himself to the door, get out the body by a rope which his semi-assistant was willing to pull on, though he refused to touch the corpse, rolled it as best he might into the coffin, and then nailed the lid down himself as his joiner-assistant had fled by this time.

Then and then only he succeeded in shaming the crowd of cowardly savages, who, according to the Parish Council's report had been "kneeling in prayer," that he might be forgiven for his brutal treatment of the corpse, into lifting the coffin by long ropes and carrying it to the grave. Really we think that by this time even the thick-headed barbarians at South Uist, must be beginning to realize that by prosecuting Dr. Lamont they have simply pilloried themselves to the shame of the country and world.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Proceedings of the Twenty-fifth Annual Meeting, Held at Chicago, October 4, 5, and 6, 1899.

MEDICAL SECTION.

DR. CHARLES T. MCCLINTOCK of Detroit, Michigan, in the Chair.

DR. MCCLINTOCK read a paper on

ENZYMES AND IMMUNITY

in which he deduced the fact that the enzymes are unorganized ferments and are directly responsible for immunity.

DR. L. H. WARNER of Brooklyn read a paper on

RECENT PHYSIOCHEMIC RESEARCHES AS TO THE PHYSIOLOGIC ACTION OF LECITHIN AND OTHER PHOSPHOROUS COMPOUNDS.

By means of numerous experiments he has demonstrated that the organic phosphorous compounds are tissue-builders, performing an important part in the tissue metabolism, especially in the causation of subsequent changes in the animal cells and controlling the formation of tissue. No abnormal conditions result if food contains a sufficient amount of lecithin, phosphocarnic acid and other phosphorous compounds. The most marked beneficial results follow their use and are, therefore, indicated in the treatment of all wasting diseases. Lecithin is always found in mother's milk, in lesser quantities in cow's milk, and rarely ever in the artificial infant's food, hence their inefficiency. Organic phosphates, lecithin and phosphocarnic acid are necessary in order to maintain perfect health. These salts are derived from any of the body tissues and especially from beef when they are to be added to any artificial foods.

DR. WILLIAM B. BURNS of Deckerville, Ark., read a paper on

SOME PHASES OF MALARIA.

The author was of the opinion that malarial and typhoid fevers are never present in any one individual at the same time; furthermore, he made the positive statement that any fever which does not yield to the proper administration of quinin is not malarial, and if typhoid has been excluded by diagnosis, the condition is due to an auto-intoxication. He cited one case of malaria in which the patient developed marked purpura hemorrhagica and hemoglobinuria which responded readily to the use of quinin and tincture of the perchlorid of iron. Another case simulating pneumonia, with the hematazoon present in the blood of the patient, however, also yielded to alterative treatment and quinin. Symptoms of abnormal renal function, such as albuminuria and hemoglobinuria, so often found in malarial cachexia, completely disappeared after the use of quinin. He has not been able to demonstrate the malarial organism in any stage of development in the mosquito, although he has found an abundance of pigment, but not of the malarial variety. He administers quinin in from 3- to 5- grain doses, every three hours, for from twenty-four to forty-eight hours, beginning at the commencement of the decline of the fever, as the plasmodium at this time is less capable of resistance and phagocytosis is at its best. In malarial cachexia quinin should be administered in 3- to 5-grain doses three times daily, preferably on a full stomach in order to avoid tinnitus and nervousness. Relapses may be prevented by 10 grain doses on the fifth, sixth, and seventh days, given at bed time.

DR. D. H. WARNER of Brooklyn remarked that Dr. Burns was bold in saying that any fever which does not yield to quinin is not malarial. Quinin is a poison only to the full-grown germ, but does not kill the spore, consequently if given for thirty to forty days it kills the germ but the spore escapes, and it may lie dormant for years, until a favorable moment arrives for it to develop and give rise to a paroxysm. The amount of chlorids in the blood constituents and in the blood-plasma exceed the total amount of sulphates and chlorids. The parasite attacks the red blood-corpuscle and destroys it. Now, if there is a superabundance of chlorids the corpuscles are not destroyed; therefore, one must administer chlorin, and it will destroy not only the organism but its spores as well.

Patients coming from the hot-beds of malaria were dosed with quinin up to 40 grains at a time, and still the parasite grew, but as soon as the patients were put under treatment with quinin simplex plus chlorin, or chlorin plain, there was neither organism nor spore left. The speaker thought that chlorin is one of the most important factors in the treatment of malaria, and it may be used alone or with quinin plain, but not with the sulphate.

DR. CHARLES L. MINOR of Asheville, N. C., read a paper, entitled

THE SUCCESSFUL TREATMENT OF A CASE OF GRAVES' DISEASE AS AN AUTO-INTOXICATION.

After reviewing the various theories of the etiology of Graves' disease, and especially the thyrogenic theory, he reported two cases in which he treated the patients on the supposition that the disease is dependent on an intestinal auto-intoxication. A positive cure resulted in one

of them. He based his belief on the constant presence in excess of ptomains in the intestine and their violent effects on the system, and especially on the gastro-intestinal tract. Treatment consisted of a strictly regulated diet, in which the starches, sugar, and table dainties were cut down to a minimum or entirely eliminated; rest at first, followed by carefully graded exercise, and good hygiene. Medication consisted of the administration of lactate or albuminate of iron, antiferments at meal-time, an occasional mercurial purge, and intestinal lavage, to which he has given the unique name of "liver wash." Large quantities of water, at a temperature of 102° F., were used and were retained half an hour. This increased the liver activity, and all the emunctories were stimulated, thus effectually eliminating all toxins. Lavage was continued at intervals for more than a year, and in one case was followed by an apparently complete return to health except for a slight almost imperceptible prominence of the thyroid. The second patient, while still presenting objective symptoms, is entirely free from any subjective symptoms.

DR. GEORGE W. WEBSTER of Chicago remarked that the treatment at present is based on an increased activity of the thyroid gland with altered secretion, which acts on an unusually susceptible nervous system. He referred to a reported case in which the patient had been treated by injections of bile to the amount of 100 grains a day on the supposition that bile acts as an antiseptic, a cure resulting. At the same time he called attention to the fact that nearly 50 per cent. of these patients get well without any treatment whatever, others by surgical means, and still others by means of various medicinal agents. This does not furnish any clue, however, as to the real cause for the increase and perversion of the the thyroid activity.

DR. HUGH T. PATRICK of Chicago did not agree with Dr. Minor in that the poisons generated in the intestinal tract and which are absorbed from it play any part in the causation of Grave's disease. These noxious substances from the bowel are etiologic factors only in so far as is alcohol, syphilis, over-exertion, etc., in any other disease, and to draw conclusions from only two cases is a practice which is not to be recommended in medical research. Proper care must be bestowed on the intestinal tract in any disease and the numerous investigators on this subject have as yet not been able to adduce anything which might be considered as a positive proof that auto-intoxication of the intestinal tract can have any bearing as a cause of Graves' disease.

After briefly referring to the various methods of treatment of this condition, the speaker mentioned one case in which the patient had been subjected to every known treatment without avail and was finally taken home in a very serious condition. All treatment was discontinued and inside of three months the patient had perfectly recovered.

DR. HOMER M. THOMAS of Chicago then read a paper on

THE TREATMENT OF PULMONARY TUBERCULOSIS BY THE INHALATION OF ANTISEPTIC NEBULÆ.

Nebulization is supportive only, but is of great value as a secondary factor in the treatment of tuberculosis. It aids in establishing a barrier around the tubercular area by stimulating cellular structure to resist the germs and their toxins. The beneficial effects of nebulization are, first, control of cough; second, relief of dyspnea; third, intimate contact of the nebulæ with much of the respiratory cavity; fourth, inhibition to the extension of the tubercular foci.

The cough is best relieved by tincture of stillingia and beechwood creosote with a lanolin base; for dyspnea expectorant combinations with carbonate of ammonia, syrup of squills and prunus Virginiana with lanolin for a base. Various other remedies were mentioned, and special attention was called to formalin in from 40- to 20-per-cent. solution, depending upon the patient's ability to bear the use of a weak or strong solution. The nebulæ penetrate wherever the air does and by means of phagocytosis are conveyed through the blood and lymphatics to the tubercular overgrowth. While the nebulæ do not reach the encapsulated tubercular area, they inhibit extension of the disease. The atmosphere of the room as well as the respiratory passages must be saturated with the medicament. Clinical experience having proved the value of vaporized medicaments in tuberculosis further trial and investigation is justifiable.

DR. T. B. GREENLY of Meadow Lawn, Ky., commended the paper, and stated that for some time past he had been using a mixture of formaldehyd and ammonia with the most salutary results. The ammonia enables the patient to bear more of the formaldehyd vapor, and the system thus becomes immune more rapidly to the toxins of the tubercle bacillus. He has lately been using urotropin, a combination of formaldehyd and ammonia, and inside of ten to fifteen days it thoroughly disinfects the sputum so that it is absolutely free from bacilli. This treatment, with the addition of tonics, increases the patient's appetite, the cavities heal more rapidly, and a speedy recovery results. Urotropin acts equally as well in bone tuberculosis. In phthisis he also uses iodin and theobromin with massage twice daily so as to secure the action of the iodin in the circulation without imposing on the stomach. Perfect satisfaction has followed this treatment in his experience with more than 100 cases of tuberculosis.

DR. CHARLES L. MINOR called attention to the fact that a combination of formaldehyd and ammonia completely destroys the action of the former, and therefore the good results which Dr. Greenly obtained could not have been due to the inhalation of formaldehyd. He expressed his gratification that Dr. Thomas regarded the inhalation of medicated vapors as an adjuvant only. In his experience patients who inhale simply the air around them do as well as though medicated vapors have been used, and pure air has the advantage of not producing any irritation whatever.

DR. J. M. PATTON of Chicago congratulated the essayist on his conservative view of the therapeutic effects of inhalation of medicated vapors. Neither inhalation nor the injection of different oils into the respiratory tract have given any definite results as far as a cure is

concerned, which really cannot be expected in view of the existing pathological changes. Councilman has demonstrated a collateral zone of congestion around the tubercular area, which does not contain tubercle bacilli, but has sufficient circulation to admit of absorption and poisoning, and these areas prevent anything from reaching the tubercular area itself. The failure of serum-therapy demonstrates the futility of reaching these areas through the circulation; nevertheless, beneficial results follow the use of these measures as they lessen the cough, diminish bronchial secretion, and improve the respiratory function. In chronic bronchitis great good follows the use of vaporization, as anything that will lessen bronchial secretion will correspondingly lessen the danger of secondary infection from the tubercular areas.

As to the possibility of considerable good arising from the absorption of the vapor through the bronchial membranes into the system, the speaker thought Dr. Thomas was illogical.

Dr. Thomas expressed his gratification at hearing of the good results which Dr. Greenly had had with formaldehyd and ammonia. Inhalation is advocated only as an adjuvant, the only value, if none other, being in the deep breathing which it excites and the psychical impulse created in the use of nebulæ, which is not the case when air is used. This effort at deep breathing is very much to be desired in the impaired respiration of tuberculosis.

Dr. William O'Neal Mendenhall of Richmond, Ind., read a paper, entitled

DO WE NEED TO THINK?

He presented a report of a peculiar case of hereditary nervous diarrhea in a young man indirectly caused by a fall of the mother producing a fracture of the coccyx. Treatment consisted in the administration of strychnin to act as a nerve tonic, and ergot to act on the circular muscle fibers of the bowel, regulation of diet, and hygiene. A complete recovery resulted.

Dr. A. M. Osness of Dayton, Ohio, read a paper, entitled

THE EVILS; THEIR CAUSES AND THE REMEDY THAT WILL EDIFY MEDICINE IN THE UNITED STATES.

The evils were held to be "mushroom schools," antagonistic pathies, overcrowding in the profession, lack of scientific spirit among medical teachers, undue ostentation, and unscrupulous intrigues in the profession. The causes of the evils are, first, paltry remuneration for professional services; second, the fallacy of a profitable notoriety. The author suggested as a remedy the regulation of schools and professorships, obligatory interneships of all graduates, conditioning diplomas revocable for unprofessional conduct, charity hospitals to be under the supervision of medical men, and the encouragement of strictly prescription pharmacies.

Dr. E. B. Montgomery of Quincy, Ill., presented a paper, entitled

TWO CASES OF TYPHOID FEVER WITH UNUSUAL COMPLICATIONS IN VERY YOUNG CHILDREN,

which will appear in full in a subsequent issue of the Medical News.

Dr. Fenton B. Turck of Chicago then read a paper, entitled

FURTHER OBSERVATIONS ON THE TREATMENT OF THE ABDOMINAL VISCERA THROUGH THE COLON.

The paper was a very interesting one, and the author dwelt particularly on the importance of colonic lavage in the treatment of all diseased conditions of the bowel. He explained his method very fully, illustrating it by a series of experimental reports.

Dr. William Barclay of Pittsburgh expressed himself as being very much opposed to the indiscriminate injection of large quantities of water into the bowel. He was pleased to learn that Dr. Turck uses only a small quantity of water, as large quantities in his experience have proved to be injurious. He especially condemned the use of syringes as they destroy the muscular tone of the bowel, and a constipation is set up which is almost irremediable. Cathartics, too, are unpleasant to use, but cathartic medication in conjunction with regulation of diet is to be recommended.

Dr. T. Wertz of Evansville, Ind., said he knew of no reason why the bowel should not give out the same as any other organ. Many persons are incapacitated for business on account of constipation, and from the constant use of cathartics their stomachs have become irritable, so that they are obliged to resort to water enemas. In cases in which there is a paralysis of the bowel or insufficient peristalsis water enemas are the best agents to make use of. Many lives have been prolonged by the use of food enemas when the stomach is non-retentive and needs a rest.

Dr. C. J. Lewis of Chicago raised the question as to whether the effect of very hot and very cold water is not the same. Peristalsis is dependant upon the stimulation of Meissner's ganglia, and the extremes of temperature may produce a paralysis of it.

Dr. H. M. Thomas of Chicago said that there is a general agreement at the present time that the saprophytic bacteria in the intestinal tract are largely the cause of appendicitis. Colonic lavage facilitates diagnosis, as one needs only to unload the bowel of its accumulated bacterial infection in order to make possible more accurate palpation of the appendix, and thus determine its condition of inflammation.

Dr. Thomas J. Schuell of Parnell, Iowa, for many years believed himself to be the originator of colonic lavage in the treatment of appendicitis. The usual idea is to unload the cecum, but by using water at 110° F. it will not only unload the cecum and colon, but at the same time will excite peristalsis of the cecum as well as of the appendix. Many cases of appendicitis are due to impaction of the colon, producing paralysis of the muscle fibers and the formation of a ball-valve action of the cecum, and by means of a slight shock, such as jumping, the fecal matter is forced into the appendix, bacterial decomposition sets in, and inflammation, necrosis, and pus formation occur. Colonic flushings should be administered every three or four hours during the first twenty-four to thirty-six hours, and after four or five flushings beneficial results are very apparent.

DR. TURCK, in conclusion, emphasized the value of using the colon as a means of treating the abdominal viscera. It is not the quantity of water so much as the temperature which procures the characteristic reaction. Hot water draws out the water from the intestines, and the original injected quantity is thus increased. The temperature raises the body temperature two or three degrees, and, like cold, is a vasomotor stimulant. Fecal matter is a normal stimulant to peristalsis, and the same effect can be produced by artificial stimulants. This can be done by means of small quantities of water. When it is desired to produce gymnastics of the blood, hot air is used, and it acts on all abdominal viscera at the same time as a stimulant.

DR. W. V. ANDERSON of Toledo, Ohio, reported

A CASE OF COMPLETE HERNIA OF THE PREGNANT UTERUS,

which will appear in a future issue of the MEDICAL NEWS.

DR. JOHN PUNTON of Kansas City, Mo., then read a paper, entitled

PATHOGENESIS OF FUNCTIONAL NERVE DISEASES AND ITS PROPHYLACTIC INDICATIONS.

In the pathogenesis of nervous diseases heredity stands foremost, as the results of injurious living on the part of the parents are often transmitted to the offspring. Pathological changes are produced in the blood which act on the nervous system in such a manner as to cause actual disease. In certain nervous diseases the red-blood corpuscles disintegrate and the plaques are much multiplied. Good diet and tonics tending to improve the system and the condition of the blood speedily restore health. In this connection the study of sociology ought to claim earnest attention as it is a most important factor in the causation of nervous diseases.

DR. PHILIP ZENNER of Cincinnati, Ohio, followed with a paper, entitled

THE ASSOCIATION OF HYSTERIA WITH ORGANIC DISEASES OF THE NERVOUS SYSTEM.

Organic diseases of the nervous system often follow hysteria, but are often obscured by the hysterical manifestations. Diagnosis is facilitated by noting the personality of the patient, relation of symptoms to organic diseases, and the clinical picture presented. Prominent among these are hysterical temperament, stigmata of disease, anesthesia, paralysis, contractures, and visual changes. In hysteria special attention must be given to globus hystericus—concentric contraction of the visual field. In organic disease the alteration of the deep reflexes, the rigid pupils and the action of regeneration must be noted.

DR. ALBERT E. STERNE of Indianapolis, Ind., then read a paper, entitled

TEMPERAMENT AND ITS INFLUENCE.

He divided temperament into the acid, alkaline, and neutral variety, each one of which causes diseases peculiar to itself. This study is still in its infancy but is one of vast importance in the causation of diseases of the nervous system and is deserving of further investigation.

BACTERIOLOGICAL DIAGNOSIS IN ALL DISEASES OF THE CONJUNCTIVA AND CORNEA

was the title of a paper read by DR. J. O. STILLSON of Indianapolis, Ind. Water currettage was advocated in certain ulcers of the cornea. A small stream either of sterilized water or antiseptic solution is thrown against the cornea with sufficient force to dislodge the necrosed epithelium and clean out the ulcer. This method has been pregnant with the most salutary results in the hands of the author.

DR. WILLIAM F. BARCLAY of Pittsburgh, Pa., then read a paper, entitled

INTESTINAL AUTO-INTOXICATION; ITS PREVENTION AND TREATMENT.

The following conclusions were deduced: Daily evacuation of the bowels will prevent decomposition of matter in the intestines and the subsequent occurrence of auto-intoxication. Rectal injections of water, for the purpose of producing a bowel movement, or for cleansing the bowel, were not approved of, but cathartics were recommended, especially calomel, papoid, salines, saline mineral waters, cold baths, etc. Proper food at regular intervals is very important.

DR. JAMES H. TAYLOR of Indianapolis, Ind., then read a paper on

INDIGESTION IN INFANTS AND CHILDREN.

The causes of indigestion, such as improper food and over-feeding, were discussed in detail. Treatment should consist of washing out the stomach, ridding the alimentary tract of all irritating matter, and regulating the diet and time of feeding. Absolute rest was insisted on. Medicinal treatment is not so essential. Tincture of nux vomica and arsenite of copper should be given.

DR. R. ALEXANDER BATE of Louisville, Ky., then read a paper on

LITHIASIS.

After referring to the etiology and symptoms, he concluded by saying that the only proper treatment of this condition is the free use of salicylates and alkalies.

DR. A. H. CORDIER of Kansas City, Mo., in a paper, entitled

NEPHROLITHIASIS,

dwelt especially on the clinical diagnosis and treatment of this disease.

DR. DUDLEY S. REYNOLDS of Louisville, Ky., read a paper, entitled

THE THERAPEUTICS OF INFECTIOUS CONJUNCTIVITIS,

which will appear in a future issue of the MEDICAL NEWS.

A CONTRIBUTION TO THE STUDY OF LUNG REFLEXES,

was the title of a paper read by DR. MARION K. BOWLES of Joliet, Ill. Attention was called to the fact that examination of the lung should be made more frequently in cases which are clearly not of lung disease, for it often clears up the diagnosis, as some trifling cause

may excite reflex contraction of the fine muscle-fibers. This is especially important in life-insurance examination.

The Association then adjourned, to meet at Asheville, N. C., in October, 1900.

REVIEWS.

Progressive Medicine—Volume III. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in Jefferson Medical College of Philadelphia. Octavo, 440 pages, 11 illustrations. Philadelphia and New York: Lea Brothers & Co., 1899.

The third volume of this new periodical well maintains the high reputation of its predecessors. The diseases of the thorax and its viscera, including the heart, lungs and blood-vessels are reviewed by William Ewart, M.D., F.R.C.P., lecturer at St. George's Hospital and physician to the Belgrave Hospital for Children, London. Though the subject is a most hackneyed one he succeeds in giving it a very practical interest. His advocacy of the pleximeter instead of the finger in percussing, though he does not include the use of the hammer in his recommendation, is very interesting. His treatment of the whole subject of pleximetry wears a novel air. The practical points as to the use of the pleximetric bones, especially the scapula, which is seldom taken advantage of for pleximetric purposes, are evidently the result of careful personal study. He shows, too, the advantage that may be taken of the spleen as a pleximeter. When the stomach is distended with gas the "boxy" note that results over the area of the spleen because of its pleximetric qualities may be used to outline it quite as successfully as the usual dulness when distention of the stomach is absent. Auscultatory friction, as practised with the ordinary stethoscope, receives due notice. Farther on there is an interesting note on the treatment of coal-gas poisoning by oxygen inhalations. In one case in which the symptoms were very severe the patient's life seems to have been saved by this means. Whenever there were intermissions in the oxygen inhalations during the first few hours threatening symptoms recurred.

Skin diseases are reviewed by Dr. Henry W. Stelwagon. Two things seem of special interest in the chapter: one that the trend of medical opinion is setting toward definitely considering lupus erythematosus as in some way a manifestation of tuberculosis. If it is not directly due to the presence of bacilli, then to their toxins. Alopecia areata, the occurrence of patchy baldness, is now thought not to be always due to a single cause, but to represent in different patients often very varying pathological entities. At times they are due to neurotic disturbances; at times they are parasitic in origin.

Diseases of the nervous system are reviewed by Dr. Spiller. The neuron theory, which has been called into question by Nissl, is discussed and the points recently brought out in the controversy on the subject are indicated. A recent contribution to the function of the posterior column receives mention. According to this the posterior columns transmit the sensations of cold, touch, and pressure and of the so-called muscular sense, but not of the other sensory impulses. Paralysis from chlorosis, from typhoid fever, and from various spinal symptoms that develop after intense anemia, and especially pernicious anemia, are touched upon.

Dr. Richard Norris reviews obstetrics. The interesting phase of the work done during the past year in obstetrics has been the study of the toxemia of pregnancy and its relations to the complications of gestation, especially to the kidney troubles of pregnancy, to pernicious vomiting, and to eclampsia. For hyperemesis gravidarum the necessity for absolute rest in the recumbent position is insisted on, and the rest-cure, especially that feature of it which separates the patient from her friends, is suggested as the most likely remedy in milder cases. In severe cases subcutaneous normal saline injections are advised, first, to supply the liquids so necessary for the tissues; second, to aid in the elimination of toxins; and third, to increase vascular pressure and give better blood-supply to the brain.

On the whole the book forms an excellent mirror of up-to date practice in the subjects treated.

Cyclopedia of the Diseases of Children, Medical and Surgical. Vol. V. *Supplement.* Edited by William A. Edwards, M.D. Illustrated. Philadelphia: J. B. Lippincott Company, 1899.

The editor of this book deserves great credit for the discrimination shown in the selection of contributors and for the thoroughness with which the subjects have been handled. It is a supplement to Keating's masterpiece and is up to date in every respect.

Ballantyne writes on "Congenital Disorders," "Diseases of the Newborn," and "Congenital Skin Diseases;" Rotch, on "Feeding in Infancy;" Barlow, on "Scurvy;" Osler, on "Cretinism;" Henry Morris, on "Surgical Diseases of the Kidneys;" Howard A. Kelly, on "Diseases of the Ovaries and Tubes;" Sachs, on "Amaurotic Family Idiocy"; Snell, on the "Hygiene of the Eye;" Jacobi, on "Pulmonary Tuberculosis;" and Cheadle on "Rheumatism." The wide range of the book will be shown by mentioning the following papers:—"The Mortality of Early Life," by Brothers; "Pica," by Small; "Swimming, Dancing and Bicycling," by Young and Spellissey; "Intestinal Bacteria," by Ely; "X-Rays in the Surgery of Children," by Keen.

The advances in our knowledge of the infectious diseases are all taken cognizance of except meningitis, on which subject, to our surprise, there is no contribution. While we believe the editor is wise in saying that "the majority of sick children are treated by the general practitioner," and "it has been our endeavor to hold pediatrics allied to general medicine," we cannot help remarking that a few of the articles are written too much from experience with adults. We also believe that certain articles could well have been omitted as belonging in books on hygiene, clinical methods, or the general text-books on surgery. Thus, for example, we do not see the necessity for the article on the hematocrit. Some of the papers are too long, and some repeat much of what is in the or-

iginal five volumes, but this is unavoidable, because, otherwise, the articles would scarcely be readable. The illustrations are numerous and very successfully executed. We must draw special attention to those in the articles on "Feeding," Bicycling," Cretinism," "Diseases of the Blood," "Appendicitis," the "X-Rays," and the plates showing the changes in the fundus in amaurotic family idiocy. The last is taken from Frost's Atlas; in a new edition it would be wise to have it in colors.

All in all, the volume is a most welcome one. It is not only a supplement to Keating's Cylopedia, but to every book on children's diseases and internal medicine.

LEITFADEN FUR DEN GYNAEKOLOGISHEN OPERATIONSKURS (ELEMENTS OF GYNECOLOGICAL OPERATIONS). VON DR. E. G. ORTHMANN, Berlin. Leipsic: Arthur Georgi, 1899.

ONE does not frequently find in a work as small as this the elements of completeness and thoroughness which characterize Dr. Orthmann's book. This is not surprising, however, to one who has taken with Dr. Orthmann the course in gynecological operations which is outlined by the author. It is complete and modern and embraces all operations in the specialty which one is called upon to perform. The book reflects the practical work and by means of the numerous and well-executed cuts makes the details of the various procedures easy of comprehension. To the student or practitioner who is familiar with German this little work can be heartily commended, especially since it represents the methods of Professor August Martin, one of the most famous and original operators among German gynecologists.

AMERICAN POCKET MEDICAL DICTIONARY. Edited by W. A. NEWMAN DORLAND, A.M., M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania. Second edition. Philadelphia: W. B. Saunders, 1899.

THE present edition of this dictionary does not differ from its predecessor except in the addition of newer words which have found their way into medical nomenclature. Although it does not pretend to supplant larger works of a similar nature, it certainly is very complete and fulfils it purpose admirably. It is a very complete little medical lexicon. Its attractive binding and thumb-index adds to its appearance.

MANUAL OF BACTERIOLOGY. By ROBERT MUIR, M.A., M.D., F.R.C.P., Edinburgh, Professor of Pathology in the University of Glasgow; and JAMES RITCHIE, M.A., M.D., B.Sc., Lecturer in Pathology, University of Oxford. Second Edition. New York: The Macmillan Company, 1899.

A LARGE number of smaller works on bacteriology have made their appearance during the past ten years, but the one under consideration easily ranks with the very best. The subject is presented with an accuracy of statement that will undoubtedly commend its adoption as a student's text-book. Much attention has been given to a lucid description of laboratory technic, the preparation of culture media, and microscopic methods in general, and the student will find the book a very valuable aid in these matters.

Only those bacteria have been described whose actions are pathogenic to man and the pages are fully illustrated, mainly by reproductions from photographs. In an appendix the subjects of smallpox, hydrophobia, malarial fever, and dysentery are considered, and a short, general bibliography on bacteriology has been added. The book contains more than 500 pages, is well printed and carefully made, and its small, handy size is particularly acceptable. It is deserving of wide popularity and we heartily commend it to all interested in the subject.

THERAPEUTIC HINTS.

For Granular Conjunctivitis.—BLOEBAUM recommends the association of sulphate of copper and salicylic acid in treating this affection, the granulations being destroyed as by elective action without injury to the healthy parts of the conjunctiva. Corneal ulcerations do not contraindicate the use of this combination of remedies, which are prescribed as follows:

℞ Ac. salicylici, Cupri sulphat., Cocainæ hydrochlorat. } aa . . gr. xv
Vaselini alb. . . . . ʒ iiss.
M. Ft. unguentum. Sig. External use.

For Gonorrheal Urethritis.—

℞ Methylene blue . . . . gr. xxv
Ol. santali., Oleoresinæ copaibæ } aa. . . gr. xxx
Ol. cinnamomi . . . . gtt. x.
M. Ft. pil. No. X. Sig. One pill three times a day.
—*Horwitz.*

For Intertrigo.—

℞ Quininæ oleat. . . . . gr. v
Lanolini . . . . . ʒ ss
Ol. olivæ . . . . . ʒ iiss.
M. Ft. unguentum. Sig. Apply twice a day by inunction.

After use of the ointment cover the part with starch powder or with the following:

℞ Ac. salicylici . . . . gr. xxx
Magnesiæ . . . . gr. lxxx.
Talci . . . . . ʒ v.
M. Sig. Powder.

For Impetigo of Face and Scalp in Nursing Infants.—

℞ Ac. salicylici . . . . gr. xv
Bismuthi subnitrat. . . . ʒ v
Pulv. amyli . . . . . ʒ ii
Ungt. rosæ . . . . . ʒ iss.
M. Sig. External use.

If the impetigo is of the dry squamous variety, use the ointment by inunction, frequently repeated. If moist, apply a thick coat of the ointment on gauze. Pruritus and congestion will rapidly diminish while the new, healthy epidermis forms under the ointment-crust.—*Kistler.*

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, OCTOBER 28, 1899. NO. 18.

ORIGINAL ARTICLES.

CERTAIN ASPECTS OF BONE AND JOINT DISEASE OF INTEREST TO THE GENERAL PRACTITIONER.[1]

BY VIRGIL P. GIBNEY, M.D., LL.D.,
OF NEW YORK;
CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY; SURGEON-IN-CHIEF TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

IT is to be presumed that all aspects of bone and joint disease should be of interest to the general practitioner, yet conditions frequently arise in the management of a case that seems to demand counsel, and the practitioner is often compelled to accede to the wishes of the family, occasionally feeling it to his interest to ask the consultant to conduct the case to a successful issue. This is not the time or the occasion to discuss the relationship which the general practitioner and the specialist maintain one to the other. The President of the Academy is desirous of calling forth discussions upon topics which shall interest the general membership. He naturally believes the sections competent to discuss the topics that pertain to different branches of medicine and surgery.

There are certain aspects of bone and joint diseases which specially appeal to the practitioner, and it shall be my aim this evening to allude to a number, and to present them in a way that should bring out a free discussion.

The injuries that commonly end in disease are not numerous, yet it is well to bear in mind that trivial injuries are sometimes followed by the most distressing consequences; that the term disease, as applied to these consequences is not inappropriate. Take, for instance, the tuberculous lesions of the bones and joints occurring in childhood. Notwithstanding the slight influence heredity is thought to play in the etiology of these affections there still remain a large number of medical practitioners throughout the country, and a still larger number of the laity, who believe that falls, bruises, and traumata of all kinds are responsible for the destructive diseases which render a child a cripple for life. A slight wrench sometimes given by the mother or the nurse, or a playmate, is followed so closely by symptoms that point unmistakably to disease of the bones that we are bound to recognize these traumata as factors, at least, in etiology. Since I have had this paper under consideration I have seen in a suburban town a child with evidences of cervical Pott's disease, who was perfectly well and free from any deformity about four weeks previously. The father was playing with the child one morning, teaching the little one how to turn a somersault, when, all of a sudden a cry was heard and the neck remained stiff from that moment. An effort was made to trace symptoms of infection prior to this date, but with unsatisfactory result. The common practice of "yanking" a child over a curb, that is, catching it by the arm or wrist, lifting it from street to sidewalk, sometimes ends in an injury to the elbow, characterized by the displacement of a tendon or an injury to the epiphysis. As a rule these injuries are trifling and no lesion follows. Occasionally the hyperemia set up in the neighborhood of the joint furnishes a fertile soil for bacilli, which may have been introduced long prior to this time into the system, and a tuberculous osteitis is the result.

Children convalescing from the exanthemata, or other infectious diseases are notoriously vulnerable, and the most trivial accidents are to be avoided. Curiously enough, the more severe traumata, such as falling from a roof or out of a window, at the height of two or three stories, or from a runaway carriage, seldom end in disease. The result of these severe injuries is immediate. Proper means for relief are at once adopted and disease rarely follows. Again, in adult life, more especially, bruises or frequently recurring blows in the same locality, end in sarcomata and other malignant growths. My attention has been called the more forcibly to this by my friend Dr. Coley, who has made a valuable contribution to the etiology of malignant disease (*Annals of Surgery*, March, 1898), and a perusal of this paper will satisfy one that malignant diseases of bone are, in a fair percentage of cases, caused by the injuries now under discussion. Calling upon my personal experience, I am prepared to corroborate the views maintained by the surgeons who have devoted much time to this subject.

With regard to neoplasms, little need be said, except in the way of urging early diagnosis. It may be asserted that an early recognition of a neoplasm is of little account so long as we are in such deplorable ignorance of a cure, still the spread of the pro-

[1] Read before the New York Academy of Medicine, October 5, 1899. For discussion see page 571.

cess may be checked, radical measures may be adopted all the earlier, and life, therefore, may be prolonged. Any occupation which renders one liable to a recurrence of blows on a given member, should be duly considered, and in that way a timely warning may be given. I recall, for instance, a paragraph in Dr. Coley's paper. He refers to a sarcoma operated upon by Dr. Bull. The patient was a dentist, and he was able to recall four or five instances in which this disease had been developed by a succession of blows connected with work about a dental chair.

I do not wish to convey the impression that repeated blows of this kind are usually followed by malignant disease. Indeed, only two days ago I saw a gentleman thirty-five years of age, who consulted me about a traumatic osteitis of the left tibia. The physical signs were quite distinct, the increase in size of the left tibia over that of the right was about one-half inch. The peculiar configuration of the bone enabled me to make a diagnosis. Now, this gentleman gave a history that three years ago, when in the bicycle business, he was subjected to frequent bruises of this shin. He was in the habit of showing the goods to the customers, and it happened that nearly every day the rat-trap pedal of the bicycle would strike against his shin. After repeated blows of this kind, he complained of pain, but it was not severe in character. He took the precaution to wear a rubber heel, and a few months later, took up another business which kept him out-of-doors. After suffering occasionally with pain in the tibia, and getting many opinions he, finally, about six months ago, fell in with a medical gentleman who gave him 20-grain doses of potassium iodid and applied some belladonna and iodin over his shin. This treatment gave relief very soon and for the past two months he has had no pain whatever. There is no lameness. I had in my mind the remarks in my paper when I examined him, and I felt pretty sure that here was a case in point, but I failed to find any malignant disease.

Repeated blows sometimes impair the walls of a blood-vessel and rupture takes place. I have seen two cases in which the blood-vessels of the gluteal region were injured. One I have already placed on record, as a case of rupture of the internal pudic artery. A lad, fourteen years of age, toward the close of the summer of 1886 was conscious of bruising his pubis, riding a bicycle. The bruise annoyed him for a few days and a little pain followed, but after resting there were no further symptoms. Using the wheel again he had some further trouble, then discontinued. Four weeks before I saw him, in consultation with the late Dr. Charles C. Lee in March, 1887, he had gone to Havana, and it was thought that he slipped and bruised his hip on the ship. At all events, the pain came on quite suddenly, and he was lame at least a week before sailing for home. En route the pain increased and disabled him very much. We found a little fulness in the gluteal region, but the result of exploration by means of a hypodermic needle was negative. Two or three days later the tumor had increased very much in size and a larger needle was inserted. Nothing but blood was found, so, with the aid of further counsel, Dr. E. L. Keyes, an incision was made on the 3d of April, 1887, into the mass. There was a large hematoma fed by the bleeding vessel, which we learned later was the internal pudic. It was so difficult to ligate that clamps were left in position and the cavity well packed. The patient died a few hours after the operation. It may be of interest to note that the opinions held by all in charge of the case were: (1) a suppurative synovitis; (2) a hematoma, which would soon undergo suppuration; (3) a neoplasm. Hip-disease was excluded.[1]

Some twelve years later, in April, 1899, I was asked by Dr. Pierson of Morristown to see a boy, eighteen years of age, of fine physical development, who gave this history: About a week before Christmas, 1898, while playing hockey, he was thrown and fell directly upon his right hip. A man quite as large as he fell across him as he lay on the ice. He was able to get up and hobble to his room, but there was a great deal of soreness about the hip. A physician was called the same day; he found nothing more than a severe bruise and ordered the patient to bed, where he remained four or five days, steadily improving. On getting up he went about stiffly, and ten days after the injury was feeling quite well, and was free from pain. He was so much relieved that he came from school in New Hampshire to his home in Morristown to spend the holidays. No attention was given to his hip. He simply was mindful that he had injured it, and for the next three months he had no difficulty in getting about. As a matter of precaution he did not indulge in any violent exercise, and on April 3d, after sitting a length of time on a hard chair, this same hip began to ache. The pain was so sharp that it rendered him quite lame as he walked to his room. On the evening of the same day there was considerable swelling noticed in the gluteal region. He returned home the next day, and when Dr. Pierson saw him the tension of the skin and the muscles over the gluteal region was quite marked; his temperature was

[1] *Medical Record*, page 241, August 27, 1887.

100° F. The patient could not lie upon his back, nor could he flex his thigh. After three or four days' rest, chiefly lying upon his face, he was able to get up and walk about the room. When I saw him I was able to confirm Dr. Pierson's observations and the question of diagnosis was not only difficult but urgent. We inserted an exploring needle and got a dark bloody fluid which looked like degenerated blood. The microscopical examination showed some freshly coagulated blood. It was difficult to tell whether some of the round cells were blood-corpuscles or the round cells of a sarcoma; the grouping, however, was not suggestive of sarcoma, so that a diagnosis was made of a hematoma, and I reinforced this by reference to my case seen some fifteen years previously. We called Dr. W. T. Bull in consultation, and the symptoms and signs suggested to him a sarcoma, though he agreed with us that it would be well to make an incision and make our diagnosis later. I made the incision under full anesthesia without delay, assisted by Drs. Bull and Pierson, and it was at least fifteen minutes after the first incision before we were able to satisfy ourselves as to the nature of the tumor. Large clots of blood were turned out, varying in size from a half dollar to one's fist. As we got near the bottom of the cavity, the clots seemed better organized. There was no fresh hemorrhage; no vessels, therefore, were tied, but simply large tubes inserted and packing of the cavity completed the dressing.

During my absence from the city, five days later, Dr. Bull was called and he found a little oozing from one of the smaller branches of the gluteal which was easily controlled. He found nothing specially alarming about the case. The progress of the patient from this time was uneventful. A trifling amount of suppuration followed. He made a good recovery and returned to school in time for commencement exercises, walking well and free from lameness.

It may be stated with little fear of contradiction, that slight injuries occurring in a patient whose ancestry is rheumatic or gouty, in a fair percentage of instances, brings out or develops rheumatism or gout and a general rheumatoid disease is developed. I have in mind two or three instances in which gentlemen, near fifty years of age, fractured the dorsal ligament connecting the second and third phalanges, and in which prompt measures of relief were adopted, and yet a general breaking up of the system, or a general development of rheumatic or gouty lesions followed in other joints. Take subacute rheumatic arthritis of the knee for instance. This is frequently induced by a slight trauma and acute synovitis follows almost immediately. Resolution seems to be established, and yet the recovery is not complete. Take, then, the three diseases that are most persistent and impair the functions of joints so frequently: tuberculosis, sarcomata, and rheumatism. All of these are certainly worthy of discussion, and present aspects that must appeal to any practitioner.

There are certain diseases that naturally end in deformity, adopt what method of treatment we may. A few may be mentioned in passing, such as rickets, poliomyelitis, tuberculous osteitis, rheumatism, gout, and neoplasms involving the epiphysis. Rachitis being a disease of malnutrition, closely allied at times to scurvy, it comes more particularly under the care of the family physician, and it is necessary to merely mention some of the deformities in order to suggest preventive measures: Pigeon breast, scoliosis, kyphosis, coxa vara, and deformities of the pelvis and extremities. The orthopedic surgeon is often called upon to correct these, and a knowledge of the cause enables him frequently to dispense with apparatus. The age, too, at which the deformity occurs, is often a contraindication to the use of appliances, except as supplemental to operative measures. The injury done to the bone by cutting operations, is, as a rule, very slight; diseases seldom develop at the site of operation. The trauma itself sometimes favors a sclerotic process, and bones, after division, are frequently stronger than they were before. The early recognition, however, of rickets and scurvy, is so essential that I am more than willing to leave a discussion to the Fellows of the Academy, and I shall pass, therefore, to the next item, poliomyelitis.

The neurologist will bear abundant testimony I am sure to the deformities and distortions of limbs that result from this destructive cord disease. The occurrence of outbreaks of multiple neuritis and poliomyelitis in certain parts of the country in the past few years has called our attention forcibly to the possible infectious nature of these diseases, and it will not be long, I am sure, before the pathologist will be able to abundantly confirm the view now maintained by men with large clinical experience. I know of no deformity of the joints more difficult to manage than that which follows a paralysis of localized groups of muscles. The spinal column, hip, knee, ankle, and shoulder, especially, present deformities that appliances and operations of all kinds sometime fail to correct. It is true that great relief may be afforded by what are called prothetic measures. Joints may be protected and muscles may be transplanted; capsular ligaments may be shortened, and even joints may be removed, substituting therefore a synostosis, which enables the patient to get about with more comfort, yet a disability remains, the lameness remains, even when the deformity is removed. It gives me pleasure, on this occasion, to refer to the

brilliant work that has been accomplished by surgeons in the relief of paralytic deformities.

Recognizing the great assistance the neurologist may render the orthopedic surgeon, we have succeeded in thus reinforcing our staff in the Out-Patient Service of the Hospital for Ruptured and Crippled. In this way we are enabled to determine more particularly what muscles may be of service if transplanted, what muscles will be of absolutely no assistance, and the advantages thus gained is already manifest. It may be asked what aspects of poliomyelitis are of special interest to the practitioner. I unhesitatingly reply that early diagnosis is that which should interest him, because the pathology is pretty well understood. The clinical history and results of the disease are also understood. Knowing, as we do, that the entire cord itself is involved at the outset, it should be our duty to limit the inflammatory process and to bring this about as quickly as possible by the use of counter-irritation or hot fomentations to the spine, or cold, or whatever methods appeals to the physician in charge. It is fair to assume that the force of the inflammation can be broken, and that ganglion cells may be saved from destruction. At the same time it is natural to presume that rest to the limbs will be the best means of restoring a muscle whose nervous supply is impaired or suspended. Protection should be thrown about these muscles, very early use is very undesirable in my judgment, and our efforts should be directed toward husbanding what strength remains. In caring for joints it must be remembered that the muscular protection is more or less removed, that ligaments will therefore stretch, subluxations are apt to occur as a result of the laxity of this ligamentous tissue, and advice of this kind I am sure is better than the advice given by the gymnast or masseur to stimulate the muscles to encourage the child to use the limb as much as possible and avoid apparatus. The whole theory of orthopedic appliances in poliomyelitis is based on protection of the joints, a conservation of muscular energy and a prevention of deformity.

Fortunately, rheumatism does not often deform a child, but there are melancholy instances in which the deformity is most persistent and most pitiable. It is in adults that we find the greatest ravages of rheumatism, but, come when it may, at whatever age, we should bear in mind that the deformities which do result are exceedingly difficult of correction, and that while the deformity itself may be overcome, the functions of the joints remain more or less impaired. Our efforts, therefore, should be all the more vigorous in the prevention of such disabilities.

I may, in passing, merely suggest the influence an empyema has upon the integrity of the spinal column and the chest walls, and to point out the importance of guarding against too great a deformity during convalescence. Some of the most distressing curvatures of the spine that it has been my misfortune to meet with have resulted from empyema.

As regards the differential diagnosis between spinal diseases and spinal injuries: By spinal injuries I mean strains, concussions, bruises and even anemic conditions, resulting in irritable spine; by spinal diseases, Pott's disease, malignant disease. While spinal injuries in children, and even in adults may occasionally end in disease, it is the rule for no disease to follow. There is usually a distinct history of trauma, followed by immediate results which soon disappear, to reappear months later. Occasionally, in cases of irritable spine the trauma may antedate by many months and sometimes a year. It behooves one, therefore, to search closely for a cause, to examine and cross-examine, especially when a gross lesion cannot be made out distinctly.

Some of the points in differential diagnosis between disease and injury are the gait, the stiffness of the column, impairment of function, and the location of the pain, whether in the course of certain nerves or whether localized. The general practitioner when called to examine a spinal case looks for tenderness over the spinous processes or lateral masses. If he fails to find any tenderness he is apt to rule out disease, although there may be a manifest deformity. Deformity may occur about the junction of the last cervical with the first dorsal, and a prominent vertebra prominens sometimes obscures the diagnosis. Not long since, in looking over a suspected case, I was inclined to regard the prominence of this spinous process as significent, when the mother remarked that it was a common deformity in her family, and had been noted for two or three generations. It may be well to state, for the sake of argument, that in vertebral disease, that is, disease involving the bodies of the vertebræ, tenderness is the exception. This is specially true in children. It is not so true in adults. I am quite aware that differences of opinion exist, but I am quite sure the orthopedic surgeon attaches very little importance to tenderness as a sign in Pott's disease. The reason is quite obvious. Since the lesion is confined to the bodies of the vertebræ, and since the nerves passing through the foramina of exit do not supply, as a rule, the spinous processes of the vertebræ involved, one need not look, therefore, for any tenderness. Why we should have tenderness in adult life I am unable to say, unless there be, as there often is, a hysterical element, a condition, perhaps, of general anemia, which makes pressure in almost any region produc-

tive of pain. Spinal tenderness is the rule in adolescence in the female, even when much deformity exists, and when one feels positive that a tuberculous lesion is present. The occurrence of irritable spine in young women, and even in older women, should prompt one always to examine the spine with regard to its function. Twist the column in all normal directions, insist on the patient going through active movements, so as to determine if there be any reflex spasm or ankylosis. The most common tests are hyperextension of the thighs with the patient lying prone upon the table, concussion, by coming down sharply upon the heels, or striking the top of the head, enabling one to determine whether the reflex spasm is excited—that is, whether the patient winces much. If a direct bruise has been made the local signs are quite distinct in the soft parts, so that one can easily distinguish between this and a destructive lesion of the vertebræ. The radiating pains in the course of nerves passing from different regions are very significant, especially the girdle like sensation one feels about the abdomen, or if in the cervical region, the occipital pains. Again when the disease involves the lumbosacral region, the symmetrical sciatic pains are significant.

Age is an important factor in differential diagnosis. For example, Pott's disease is less likely to occur in adolescents or adults than in children. The character of the pain will enable one frequently to differentiate between a malignant disease of the vertebræ and a tuberculous lesion. In malignant disease the pain is excruciating and persistent in spite of remedies. In tuberculous disease the pains come in exacerbations, and are not, as a rule, severe, but are annoying, and nagging in character. The gait may be the same in the two, yet in the tuberculous disease there is usually deformity. The aspects which appeal to the practitioner are the absence of deformity in incipient Pott's disease, the rigidity of the column, and the general behavior of the patient. A very common expression in certain parts of the country is that the child doesn't handle itself naturally. It will get up and down awkwardly, will grunt and groan during its sleep, the sleep therefore being disturbed; it will walk peculiarly, assuming a gait that is typically spinal in character. The steps are short and every precaution seems to be taken to avoid concussion.

The disease of the spinal column which simulates Pott's disease of the spine is rheumatic spondylitis, sometimes called arthritis deformans of the spine. By way of illustration, allow me to report briefly two or three cases bearing upon this point. A gentleman about fifty years of age came under my care in September, 1898, for a condition of his spinal column which had been regarded by one physician as lumbago, another as an irritable spine, and still another as rheumatism. He presented a right rotary lateral curvature in the dorsal with a compensating curve in the lumbar to the left. There was also a little anterior curvature in the lumbar region. The ileocostal space on the right side was deeper than on the left. There was no psoas spasm. Concussion was painless although he had radiating pains down the thighs. There was marked stiffness in the dorsal-lumbar region. The history he gave was that of a rheumatic attack. I failed to get the angular prominence, and yet I could not make a hard and fast diagnosis. I determined to treat him with potassium iodid in increasing doses, and at the same time to give him a support to his back, and made him a plaster-of-Paris corset, which did not give him relief until I got sufficient pressure against the lumbar spine to give him a sense of security. From that time to the present he has improved. I am satisfied to-day that he has no Pott's disease of the spine, that his case is purely one of subacute spondylitis, and I merely refer to this in order to contrast another case, that of a man thirty-five years of age, referred to me a few days ago by Dr. Bachmann of this city. In this patient I had no difficulty in making out a case of rheumatic spondylitis, with ankylosis of the entire column. Seventeen years ago he had an attack of gonorrheal rheumatism, which lasted three or four weeks. A few years later he had an attack of sciatica, lasting nearly a year. He gets cold easily and it is always necessary to take extreme care of himself. Five years ago he began to stoop a little. His deformity has increased a little since that date. He has the girdle pains, especially after much exercise. I found a posterior curvature of the spine from the fourth cervical to the twelfth dorsal, where there was a slight projection of a spinous process. There was marked tenderness in the upper dorsal and in the lumbar. The column was rigid throughout; as he lay upon his back he could not get his head to the table without great effort. I had him lie prone and he was obliged to rest upon his elbows and knees. He simply could not get his abdomen to the table.

I have already reported cases of typhoid spine, which have excited more or less interest, and which I now introduce merely as a contribution to differential diagnosis. These are cases occurring either during the attack of typhoid fever or toward the close of convalescence. There is exquisite tenderness, both on pressure and on movement. There is no deformity. The diagnosis is made on the history chiefly, and on the promptness with which it responds to treatment, such as the Paquelin cautery,

adhesive strips to the spine, which give a moderate degree of support, and occasionally a light steel apparatus.

I recall the case of a gentleman, twenty-eight years of age, seen in consultation with Dr. Henry S. Stearns of this city, on December 26, 1896. About the middle of July he had an attack of typhoid fever, which was practically a walking case. At no time were there any alarming symptoms, but from the beginning he complained of pain in his back. At the end of five or six weeks he was convalescing; he still complained of an occasional pain in his back. In the latter part of September he made a misstep, felt a sharp attack of pain in his right side, lumbar region; after a little rest he felt better, and two or three weeks later while flying a kite one day, he strained himself, and the pain was so sharp as to double him up and cause him to fall to the ground. From that time his pains were more and more frequent, more easily induced, and six weeks prior to the date of my seeing him he was brought to the city with considerable difficulty. It was necessary to transport him on a mattress on the train, and from the train in an ambulance to his home. Lateral movements caused pain; he was in a state of terror all the while lest some one should move him, and I found, on examination, a point of tenderness over the lateral masses of the first and second lumbar vertebræ. The examination was exhausting and therefore was not thorough. He described the pains quite graphically as shooting down the course of the anterior crural. I advised the use of the Paquelin cautery three times a week and made him a Knight spinal brace. I saw him occasionally during the next two months, and at each visit found him greatly improved Added to his typhoid spine was a neurosis of the spine which lasted well into the following year. During last winter I saw the gentleman at one of the clubs, and he reported that he was perfectly well, attending to business, had long since discarded his apparatus, and that his cure was complete.

It is astonishing how seldom the general practitioner makes a diagnosis of Pott's disease before deformity arises. He is so apt to disregard the history of the case, and is so apt to rely on physical signs, such as the angular projection of a spinous process or two. He rather waits for this feature of the disease before making a diagnosis, and complaints are frequently lodged against the family physician for failing to recognize the lesion at a time when restoration without deformity, and sometimes without impairment of function, is possible. A certain number of cases, on the other hand, of irritable spine are treated by plaster-of-Paris jackets and cumbersome apparatus for many months, and even years, on an error in diagnosis.

Rachitic curvatures are also diagnosticated as Pott's disease, and grave prognoses are given in cases in which relief soon follows.

A certain number of cases of Pott's disease begin with a slight lateral curvature, and it is a pardonable offense to mistake a true Pott's disease for a lateral curvature. A thorough examination, however, ought to elicit stiffness of the column, and tenderness on concussion, and one should, after such an examination, be able to distinguish between the two. These lateral curvatures that precede Pott's disease usually occur in young children, and the infrequency of a true lateral curvature at this period should excite some distrust; should lead one to look with suspicion upon the case, and to give the patient the benefit of the doubt. Protective apparatus should be employed until a diagnosis can be made.

In summing up the points in diagnosis I should say that a careful examination of the patient in a state of nudity is about the best means of arriving at a correct diagnosis.

Acute Affections of the Hip and of the Knee.—It is of great importance to know what affections are acute, and to this end I propose to call attention to a few which happen to have forced themselves upon me during a long experience. Take a phlegmonous periarthritis, sometimes dependent upon a bursitis, often upon a severe bruise. The soft parts are involved, the joint is not tender, but certain movements cause pain. If one can determine, therefore, whether the affection is phlegmonous in character or whether the bursa alone is involved, it will be easy to give a good prognosis, and thus save the patient from a long course of mechanical treatment. An acute suppurative arthritis may results from infection. Within the last six weeks I have seen a patient, a boy, with an acutely deformed hip, attended by much swelling about the joint, suffering night and day, and where, after a little observation, I found an ulcer over the ligamentum patellæ, which had resulted in an infectious process. The swelling about the hip proved very soon to be a large abscess, periarticular, and was relieved by incision. It was not necessary to employ apparatus; the deformity subsided soon after evacuation of the abscess, and I was enabled to give a good prognosis, that is, that the limb would be free from deformity and free from disability. A perinephritis, which is an acute process, will involve the psoas and iliacus muscles and produce deformity of the hip; a perityphlitic abscess will do the same.

Neuroses of the hip, while not specially acute, may produce deformity which is easily corrected.

Most of the acute processes are accompanied by a rise of temperature, general malaise, and such other conditions that are thoroughly recognized by the family physician. It is important, therefore, that he should know what affections are acute and what chronic. It is well to bear in mind that the acute processes, even an acute suppurative arthritis, in an infant, is remediable, and may be so treated that deformity will not result. If, however, the joint itself is involved by this acute septic process, it is difficult to give a prognosis until radical measures shall have been most thoroughly employed. If one can diagnosticate a lesion of this kind the sooner an incision is made the better it is for the patient. It is poor practice, in my opinion, to await further developments. Now, what has been said about the hip may be said with equal force about the knee.

I do wish, however, to report a case of scurvy occurring in a baby thirteen months of age, seen in consultation with Dr. Lloyd of Brooklyn, March 15, 1897. Without going into the details of the examination, a typical case of scurvy was recognized, and a tumor just above the right knee complicated the diagnosis; both limbs were excessively sensitive, but this tumor was suggestive of a sarcoma. I was enabled, however, to exclude this on account of the prominent symptoms of the disease just mentioned, although the needle of the aspirator failed to afford evidence one way or the other. I was aware that hemorrhages took place under the periosteum, and I felt that this was but part and parcel of the scurvy. The child died quite suddenly on the 23d of March, less than ten days from the time of my first visit, and Dr. Holt made the autopsy. He found the lungs, liver, and spleen spotted with effusions of blood, and on the top of the liver there was an extravasation about the size of one's thumb. The knee tumor, which had given rise to so much anxiety during life, proved to be an extravasation of blood under the periosteum, producing complete separation of the lower epiphysis of the femur. The joint itself was found normal. This case has already been reported by Dr. Holt to the American Pediatric Association in 1898.

The literature of the present day is full of the pathology and clinical history of chronic affections of the hip and the knee, such as tuberculous disease of the epiphysis, osteomyelitis, sometimes chronic and more often acute, rheumatic arthritis, arthritis deformans, and tabetic joint. All textbooks contain chapters that are sufficiently clear to enable any physician to recognize the nature of these diseases, and to put him, therefore, on his guard. Thus the points in differential diagnosis will interest us more particularly and it may be at once stated that in a tuberculous hip or knee lameness is an early symptom. Atrophy comes early; the reflex spasm is almost pathognomonic. All of these points should be duly considered. A lameness, for instance, which is very insidious, is the kind to which I refer; not a sudden loss of power, but a lameness which is recognized only at certain times of the day, becomes more and more marked in the course of two or three weeks, and which becomes specially marked during exacerbations. All diseases of this kind, it must be remembered, are characterized by exacerbations dependent upon trauma. The first exacerbation is seldom significant. The second, third, and fourth are more and more marked, and it is important that there *should be no more than the second.* The disease should be recognized at this period, and prompt measures should be taken to guard against further invasion of the disease as a result of trauma. The atrophy may not be significant; it may be very slight, especially if the child has not used the limb, and one is often tempted to look upon the atrophy as the result of disuse. A careful discrimination should be made, and proper attention given to all evidence of this kind. The reflex spasm is sometimes difficult to find. In making an examination one should not be satisfied with a few movements of the joint over small arcs, but the normal limit should be attempted by passive movements. For instance, the sound limb should be flexed to its full limit, and then the affected limb flexed to its full limit. The difference is usually very appreciable. As the limit is approached on the affected side a reflex spasm occurs, the child winces, resists, and the muscles seem to be on guard. The same is true of extension, hyperextension, rotation, abduction, and adduction. All movements should be made comparatively. The sound limb should be made use of in the test. The knee affords better opportunity for accuracy in diagnosis, in that the change in contour is an early sign. There is not, as a rule, much joint effusion, but there is an infiltration or a thickening, so to speak, about the condyles, around the patella, and sometimes about the head of the tibia. These points of thickening are usually recognized. They are "boggy," and this term well expresses the condition. The laying of one's hand over them elicits a certain extra heat, pressure brings out tenderness, and the absence of any acute process enables one to make any early diagnosis.

The point that should be dwelt upon again, and I purposely reserved it to the last, is the persistence of the lameness. There is no period during the time the child is on its feet that the lameness is not present. It may be very slight. It may, however,

simply be a favoring of the limb. The step may not be quite so long yet the mother is a very close observer and will tell you that there has been no absolute remission. If one can satisfy one's self that there have been periods when there was no lameness whatever, then hip disease may be excluded in the diagnosis. It is well, however, to regard this persistent lameness as pathognomonic. Let me illustrate this point by the narration of a case which first came under my observation on the 23d of May, 1898, in consultation with Dr. Vedder of this city. The child was seven years of age and the paternal family history was distinctly rheumatic as well asgouty. The mother's family history was also rheumatic. The child had no lameness of any kind until five or six months prior to the date mentioned, say the latter part of 1897, when, without any special cause, she favored the right knee and was partially disabled for a few days. She made a complete recovery and the lameness entirely disappeared. Two weeks prior to the date of my seeing her, say five months after the first attack, she complained of pain in the right thigh and knee, and the limb was apparently lengthened. She had a distinct hip-limp. The doctor regarded the case as rheumatic—put the little patient to bed. The result of my examination was negative. I was obliged to render the Scotch verdict "not found." Within a few days, recovery was complete. On the 22d of August, 1899, more than a year later, I saw her in consultation with Dr. Bell of East hampton The history of this attack was that, on the 14th of August, she complained of a little pain in her right knee, especially on the inner side. She was lame. The limb was apparently lengthened, although flexed a little at the hip. The doctor found it difficult to make complete extension. I learned that she had been bathing a week or two previously, and been playing on the beach with nothing on save the bathing suit. At the time of my examination I found a little resistance to extension. Dr. Bell had found resistance not only to flexion but to abduction and adduction as well at the date of his examination. There was no atrophy, no night cry, and I learned that during this omission of twelve or fifteen months there was absolutely no lameness. I excluded hip-disease, looked upon the case as rheumatic, and under antirheumatics she made a prompt recovery. On the 19th of September I had the following note from Dr. Bell: "Nothing to report on the little patient except a complete recovery. In a week's time there was no pelvic tilting present."

The change in contour and the reflex spasm may mean malignant disease. The case to which I referred in the beginning of my paper is one in point: A young women, twenty-two years of age, consulted me about her knee. She was wearing a plaster bandage applied at one of the clinics, and she had worn this for eight or nine months for tuberculous disease of the joint. I got a history of slight injury occurring some twelve or fifteen months previously, a history of lameness and pain, and found on examination a distinct change in the contour. The patella was indistinct, movements caused pain; I found a serpentine area of fluctuation on the outer side extending down under the ligamentum patella. I failed to note the condition of the patient; I failed to remember that localized areas of fluctuation are significant of malignant disease. I felt quite sure that pus was present, and that a prompt evacuation would result in marked relief. Although I failed to obtain pus by means of an aspirator I still adhered to my diagnosis, made an incision and found the whole lower end of the femur involved; in fact, only a shell remained. This patient, it is only fair to say, had really suffered very little, and the acute lancinating pains were absent. I felt chagrined, however, at not having made a diagnosis before the incision. The contents of the tumor were examined and a giant-celled sarcoma made out. An amputation at the hip-joint resulted. This was done most dextrously by my friend Dr. John B. Walker, to whom I referred the case in the Memorial Hospital.

I wish to call your attention, however, to the difficulty of diagnosis between chronic tuberculous disease of the knee in an adult and maglignant disease. These are aspects that appeal to every one. A diagnosis may only be reached by an exploration, yet it is sufficient to know that sarcomata are rather frequent in adults, and that tuberculous affections are not so frequent. An adult, it is true, may have tubercular disease which has lasted from early childhood. Recovery may have been partial, but never complete. The history, however, will enable one to discover all this, and great care should be taken in the examinations. The influence of hygiene and medication on chronic tuberculous affections is certainly worthy of your consideration. I take pleasure in calling your attention to this phase of the subject.

I am perfectly willing to admit that the orthopedic surgeon may be carried away by his apparatus or by the operative procedures. He naturally feels that his patient should be put in such a condition that an out-of-door life may be led, and he therefore feels that medication is of little consequence. Many, I say, are pessimists in therapeutics; many feel that there are few specifics, yet it is important to bear in mind that the general health should be kept above par, or at least to that point. The various tonics and nutrients can be employed with

great advantage. Hygiene is especially important, and this aspect of the disease must appeal to all.

Enough has been said already to make a repetition unnecessary, although I may be pardoned for calling attention to early diagnosis in all diseases that end in deformity, an early diagnosis of all injuries that end in disease, and of a study of all points in differential diagnosis.

TYPHOID FEVER IN VERY YOUNG CHILDREN, WITH A REPORT OF THREE CASES WITH UNUSUAL COMPLICATIONS.*

By E. B. MONTGOMERY, M.D.,
OF QUINCY, ILL.;
EX-SURGEON TO THE ILLINOIS SOLDIERS' AND SAILORS' HOMES, AND SURGEON TO THE BLESSING HOSPITAL.

No subject is of greater interest to the general practitioner than that of typhoid fever. Like the poor, it is always with us, and in the United States, at least, with the exception of tuberculosis, it is the source of greater mortality in our larger cities than any single ailment with which the medical man has to deal. According to statistics collected by Dr. F. S. Crum, and published in the *Medical Record* for August 12, 1899, during the past ten years in the twenty-four largest cities in the United States, the total number of deaths from this cause alone has been 41,931, representing not less than 600,000 cases of this preventable disease. Occurring at all ages, and giving rise to numerous complications and sequelæ, surgical as well as medical, no one subject has been the occasion of a greater amount of study and research, or has a more abundant literature relating to all its phases. The two cases which inspired this paper were of interest to me as occurring in children, and as presenting complications not frequently found at this period of life. Indeed, cases in the first year of life are exceedingly rare. Dr. J. C. Wilson[1] quotes Murchison as showing as a great rarity to the London Pathological Society in 1864 the intestines of an infant, six months old, who had been attacked by the disease at the same time as her mother. Holt[2] has never seen a case in a child under two years of age, and he quotes Northrup's report of 2000 autopsies on children, in none of which were any typhoid lesions found under that age. Lartigau[3] and others, however, have reported cases of typhoid fever in which the Widal reaction was obtained and the bacillus typhosus was demonstrated in the spleen and mesenteric glands, and yet the autopsy revealed absolutely no intestinal lesions. Ashby and Wright[4] find it very uncommon under three years, and Goodhart[5] had two patients under one year old with the disease, both cases proving fatal. Earle[6] cites a case of his own in an infant aged twenty-four months, in which death occurred from intestinal hemorrhage. He also cites a case reported in the London *Lancet* for January 2, 1892, by Ogle, in which the child was but four and one-half months old, and quotes Murchison as having had three cases in infants under a month old. He further quotes Vogel as having had seven patients under one year of age, Henoch as having had eight under two years, and Montmollin fifteen of the same age. A further case in an infant of eight months is reported by England of Montreal. Donkin[7] thinks the disease extremely rare under two years of age, and Parrot, Friedleben, Bouchut and Jules Simon do not consider that the disease ever exists among nurslings. The Widal reaction would, of course, be of use in settling this question in doubtful cases. Dr. J. P. Crozier Griffith[8] has found this reaction in an infant born while its mother was still suffering from typhoid fever. The same writer in another contribution,[9] says that an increasing number of cases is being reported in infants, and thinks that infected milk is the cause of many of them. He quotes Morse, however, as not having had a patient as young as two years among 284 children ill with the disease, and Bouchut as denying that it ever occurs among the new-born. Berg, he says, in analyzing 1626 cases occurring in Curschman's clinic, found only five patients as young as two years of age, and Filatow found none so young among 106 cases in children up to thirteen years.

From a paper by Dr. Stowell[10] on "Enteric Fever in Children," and one by Dr. Noyes[11] on "Enteric Fever in Infancy," read before the Section on Diseases of Children of the American Medical Association in 1895 I still further note the rarity of this disease in early life. Northrup is quoted as being skeptical of its occurrence in infancy, not one case having been observed in the New York Foundling Asylum in the twenty years of Dr. O'Dwyer's experience there, or in his own twelve-years' connection with the same institution. The same report comes from the Nursery and Child's Hospital in New York, and Dr. Page, the resident physician in the Children's Hospital of Philadelphia, the largest service in the United States, has never had a case there in an infant. Stowell, in his elaborate tables, only succeeded in collecting reports of 85 cases in children under three years of age. Since his report I note one case reported to the Washington Obstetrical and Gynecological Society, December 20, 1895, by Dr. Samuel S. Adams[12], in an infant of two years, the child presenting very marked meningeal symptoms. Dr. A. D. Blackader[13], in a paper read be-

* Read at the annual meeting of the Mississippi Valley Medical Association, held at Chicago, Ill., October 3-6, 1899.

fore the American Pediatric Society in 1896 also reported a case in an infant two years of age, there being present, also, marked enlargement of the liver.

In the recently published book of Dr. Hare, "Medical Complications and Sequelæ of Typhoid Fever," I note many additional cases in children under two years of age not given in Stowell's tables. Dr. J. H. Lee[14] of Cleveland reports one case in an infant of six months, and O'Malley[15] three cases at twenty-one months, three years, and six years in one family. Boobyer[16] records an instance in which out of a family of eight persons, five became infected through an infant aged eight months. The child had been restless and had constant diarrhea, but the fact that it was suffering from typhoid fever was not recognized. Osler states that perforation of the bowels from this cause has occurred in an infant five days old. Sbrana[17] has treated seventy-two cases of typhoid fever in children in Tunis, and found in some of them the complications of meningitis, parotiditis, aphasia, orchitis, and empyema. Hare maintains that in many cases in young children the disease is not correctly diagnosed, being often called "simple catarrhal fever," a term, he says, which covers a multitude of diagnostic sins. He calls attention to the fact long ago pointed out by Liebermeister that typhoid fever may occur in adults with mild symptoms and be so designated.

Case I.—J. L., female, aged nine months, of healthy parentage, nursing but partly bottle-fed, began to sicken about Feburary 26, 1897. She passed restless nights, awakening frequently with a sharp cry. She soon began to be fretful and restless through the day and her temperature to go above the normal, reaching 101.5° to 102° F. in the afternoons. Then vomiting of nourishment and water began, which continued entirely uninfluenced either by the frequency, amount, or character of the nourishment given. Some diarrhea then supervened along with the vomiting, tnere being from two to five stools a day attended by considerable pain and flatulence and some meteorism. With increase of pain and restlessness, the brain symptoms became more marked and strabismus and retraction of the head developed, in fact the entire symptom complex was that of meningitis. Her temperature meantime ranged from 102° F. in the morning to 103° or 105° F. in the evening. The cerebral symptoms increased, *tache cerebrale* became marked, and when not crying the little patient lay in a comatose condition. Finally convulsions supervened which left her apparently moribund.

I felt very sure that I had a tubercular meningitis to deal with and at this time gave an absolutely unfavorable prognosis. However, aided by a most excellent and determined trained nurse, the battle was still kept up, tepid baths given at frequent intervals, and such sedatives as potassium bromid given during the period of convulsions, and the patient breast-fed as soon as she was able to take anything in the way of nourishment. Her temperature gradually subsided, the enteric trouble lessened, the stomach became more tolerant, and one by one the meningeal symptoms disappeared, until on April 4th, about five weeks after the onset of the illness, the little one was fairly convalescent though still very weak and emaciated. Dr. A. F. Rooney of Quincy, Illinois, kindly saw the patient with me in the early part of the illness. At this writing, after a lapse of 2½ years, no more robust, healthy, and well-grown child is to be found than this little girl, not a trace of the serious brain trouble having been left behind.

The first question in connection with this case is one of diagnosis. The Widal reaction was not obtained, the test at that time not being in general use. But there was, first, a continued fever of gradual onset and long duration, with no existing condition of the throat or lungs to account for it. Then there were present the gastro intestinal and meningeal symptoms so frequently found in the typhoid fever of infancy. Dr. Rocaz[18] states that vomiting in this disease is frequent enough in children to beregarded as a part of the regular train of symptoms. Wilson says that vomiting occurs much more frequently in childhood than in grown persons, and may occur throughout the whole course of the sickness. It is more apt to be present in severe than in mild cases, and tends to increase the resemblance between enteric fever and tubercular meningitis, rendering the diagnosis for the time obscure. Griffith says that vomiting is a frequent initial symptom. He quotes two cases of obstinate, uncontrollable vomiting in children suffering from this disease, reported by Moussous, lasting in one instance eight, and in the other ten, days almost without intermission, yet followed by recovery. He has himself seen one case, running a course rather mild than severe, in which the child at last developed uncontrollable vomiting which lasted for days and ended in death. Rotch[19] says: "In my experience typhoid fever in young children is the disease which, next to non-tubercular meningitis, is most likely to simulate and be mistaken for tubercular meningitis We may also have considerable difficulty in differentiating tubercular meningitis from the non-tubercular meningitis which may occur in the course of typhoid fever. The extreme cerebral congestion which at times arises as a symptom of typhoid fever may also add fresh difficulties to the diagnosis."

In my case the absence of leucocytosis was the only point favorable to the diagnosis of typhoid fever rather than tubercular meningitis. Noyes[20] gives the history of a similar case in an

infant, aged eleven months, the infection being due to the milk used. The later history of this case followed a course which he says he has not found at all uncommon in recorded cases of typhoid fever in infancy, characterized as it was by certain symptoms which simulated meningitis. Along with vomiting and general irritability stiffness of the neck and opisthotonos developed, and irregular and convulsive movements of one arm and leg. There was not, however, as in my case any coma nor the well-marked *tache cerebrale*. Many other cases have been reported in children presenting a complete picture of meningitis complicating the typhoid fever, as one reported by Brown in the Montclair epidemic, in which there was great restlessness, tossing of the head from side to side, rigidity of the muscles of the neck, opisthotonos, strabismus, and hydrocephalic cry, in which there was complete recovery after twenty-eight days. Similar cases have been reported by Gerhardt, Simon, Rilliet, and Barthez. Griffith reports a case which he calls "meningitic typhoid fever" in a child which he thinks of rare occurrence. In this case the patient became unconscious and the *tache meningitique* became well marked on the abdomen; apyrexia was established on the 19th day, followed by rapid recovery. In this case the presence of the Widal reaction cleared the diagnosis of what appeared to be a case of meningitis.

Keen[21], while finding but few cases of meningitis recorded as a complication of typhoid fever, is inclined to think it more frequent than generally supposed. Hare[22], however, says that Osler has recorded three cases in which he made autopsies in suspected typhoid meningitis and did not find true inflammation. He further states that Taupin, in 1839, found on autopsy that in the typhoid fever of children with meningeal symptoms the condition is one of effusion without hyperemia. He further quotes Hirt in his work on "Diseases of the Nervous System," to the effect that of all diseases typhoid fever is most likely to be mistaken for meningitis. He further shows the rarity of true typhoid meningitis by the fact that from 1855 to 1887 there are only five cases referred to in the Index Catalogue of the Surgeon-General's Office. Its rarity is still further shown by the fact that out of 2000 cases in Munich only 11 are recorded in which the patients suffered from meningitis. In every case of true typhoid meningitis, so far as recorded, death has occurred. This, he says, does not possess great prognostic value, since an absolute diagnosis of true typhoid meningitis cannot be made during life. Keller[23], however, asserts that true meningitis in a child can be differentiated from typhoid fever with meningeal symptoms by the presence of "Kernig's sign" in the former, which is as follows: The child is placed in a recumbent position with the legs completely extended. Then it is raised to a sitting posture, when, if meningitis is present the knees become flexed and cannot be straightened out until the dorsal position is resumed. Hare does not consider the cases of Senn of Geneva, reported in 1825[24], as meningitis complicating typhoid fever in children as really having been meningitis, but as only representing meningeal irritation.

Case II.—M. McC., aged three and one-half years, began to sicken with fever and general malaise May 16, 1897, her temperature ranging from 101° F. in the morning to 103° or 104° F. in the afternoon. Associated with this there was more or less vomiting and headache and rapid prostration. The vomiting was controlled after some days by the use of dilute hydrochloric acid in 5-drop doses, the excessive temperature by tepid sponging and the administration of muriate of quinin in 2-grain doses every four hours, and the pain, flatulence, and diarrhea by camphorated tincture of opium in 10-minim doses at intervals. Frequent sponging with cool or tepid water was made use of throughout the continuance of the fever. Her temperature continued to range between 102° and 104° F., until the twenty-third day, when a double parotitis had fully developed, and it ranged higher, and within a few days evidence of pus formation was present. On June 14th, the twenty-eighth day, Dr. C. E. Ehle, administering the anesthetic, I freely incised and drained both parotid abscesses and kept them packed with iodoform gauze. The services of a trained nurse were invaluable in this case and largely contributed to its favorable outcome. The child's temperature remained high for some days, reaching 105° F., then gradually declined, reaching the normal about July 1st, the thirty-fifth day. Prior to the beginning of her illness she had already acquired a considerable vocabulary for one so young. During her illness she lost the power to utter a single word, and did not begin to talk again until July 14th, two months from the beginning of her illness, when she gradually resumed her accustomed speech.

Dr. Keen, in his work before quoted, has collected reports of but 75 cases of this complication in typhoid fever. In a tabulation of a very large number of cases made by Dr. Westcott, only 28 cases of parotitis occurred, 12 of them being bilateral, suppuration occurring in 7, the mortality being 30 per cent. Nine of the cases were in children under 15 years of age. It happened during the third or fourth week most frequently, but in one case, reported by Gilbert and Fournier, suppuration of both parotids occurred as early as the tenth day. Hoffman[25] is stated to have met with suppurative parotitis in 16 cases out of 1600 patients ill with typhoid fever, and that 7 of

them died; ordinary parotitis occurred in three cases. None of the writers on diseases of children, except Holt, has anything to say of parotitis as a complication of typhoid fever, and from this as well as its general infrequency I assume that it is not often met with. Aphasia seems much more common; indeed Hutinel[26] tells us that it always occurs in children. In all of the cases mentioned recovery rapidly ensued.

By the courtesy of Dr. C. W. Rook of Quincy I am enabled to report another case of typhoid fever in a child aged three years, it not having been previously reported and having come under his care August 16, 1896. Dr. Joseph Robbins of Quincy saw the patient in consultation with him. Stewart C., aged three years, had a continued fever with a range of temperature between 101° and 104° F., vomiting and diarrhea being present during the first week of the illness. On the seventeenth day swelling of the right submaxillary gland developed, which ended in suppuration. The abscess was evacuated, and subsequently suppuration occurred in the parotid gland of the same side. One week later, or on the thirty-third day of the illness the child died, the elevation of temperature having persisted to the end.

I can find record of but three other cases in which enlargement of the submaxillary glands complicated typhoid fever. The first was in that of Hoffmann, in which the swelling began on the fourteenth day of the disease and in a few days ended in suppuration and the patient's death. The second is the one reported by Gerloczy, cited by Hare, in which the patient, a girl aged fourteen years, suffered from typical typhoid fever, with swelling of the submaxillary glands of both sides. The third was one reported to the College of Physicians of Philadelphia by Dr. D. Milton Miller[27], in which the swelling of the submaxillary glands of both sides began on the twenty-seventh day of the disease, and by the fortieth day had subsided without suppuration.

THERAPEUTICS OF INFECTIOUS CONJUNCTIVITIS[1]

By DUDLEY S. REYNOLDS, M.D.,
of Louisville, Ky.;
Professor of Ophthalmology, Otology, and Medical Jurisprudence in the Medical Department of the Central University of Kentucky;
Surgeon to the Eye and Ear Department of the Louisville City Hospital.

Infectious conjunctivitis must be understood to include all forms of conjunctivitis that are contagious or communicable from one person to another through various media. It must also include those cases of staphylococcus infection arising from dust. Clinically considered the mildest form of mucopurulent conjunctivitis, whether in the newborn, in the child, or in the adult, arises necessarily from a common cause. It is the form of conjunctivitis which was long known as the catarrhal. To Dr. Weeks of New York, Dr. Gifford of Omaha, and Dr. Heine of Chicago belong much credit for their experimental labors in determining the specific ferment which produces this type of conjunctivitis. Its course is not only milder and slower than the purely purulent types, its sequelæ less grave, but it is vastly more prevalent than any of the purulent forms of infection.

It is somewhat difficult to differentiate active mucopurulent conjunctivitis from a mild type of the purulent infection. Gifford, Morax and Axenfeld have found the pneumococcus during endemic outbreaks in the exudate. Dr. Burnett of Washington has been able to confirm these observations. It is clear, therefore, that the bacillus of Weeks, the pneumococcus of Friedlander, the diplococcus of Fränkel, and the micrococcus Pasteuri of Sternberg each cause a slightly different form of mucopurulent conjunctivitis. There may be others still undiscovered In all of them, however, in addition to the light colored pus in the inner canthus, there are

[1] Read at the annual meeting of the Mississippi Valley Medical Association, held at Chicago, Ill., October 3–6, 1899.

shreds of coagulated mucus in the retrotarsal folds of the conjunctiva. The lids are not much swollen. The exudation, drying on the lashes, causes them to adhere by agglutination. Corneal abrasions are rarely seen in any one of the varieties of this type of infectious conjunctivitis. The infecting ferment rarely takes entire possession of the contents of the mucous follicles of the conjunctiva. Consequently swelling of the lid is not great, invasion of the nutrient canals of the cornea does not take place, and chemosis does not occur. The therapeutic indications are for frequent and thorough removal of the infecting matter by ablutions or irrigation with such mild unirritating saline antiseptic fluids as will aid in the solution of the coagulated material, so sterilizing the surface of the membrane as to retard the growth of the micro-organisms, and at the same time possessing soothing and unirritating properties.

Since the terminal nerves in the surface of the conjunctiva are irritated by ablutions which do not contain chlorid of sodium it is manifestly clear this salt should constitute one of the ingredients of any solution to be employed for irrigation. Borate of sodium, in solution, containing a small portion of the chlorid, with enough carbolic acid to counteract by its anesthetic effect the mechanical irritation of the frequent and prolonged flowing of the stream from the irrigator over the surface of the membrane constitutes an all-sufficient and rational plan of treatment. The long-established and irrational practice of attempting to cut short infectious conjunctivitis by the application of caustics may be held responsible for nearly all of the disastrous sequelæ heretofore ascribed to all the varying forms of infectious conjunctivitis. In cases of mucopurulent conjunctivitis caustic applications lead to entropion, symblepharon, cicatricial opacities of the cornea, more or less deep seated, and xerosis of both cornea and conjunctiva; in fact, all those deformities, cicatrizations, atrophies, sphacelations, and staphylomas formerly attributed to catarrhal and purulent ophthalmia are but the natural results of the caustic treatment employed.

Mr. Benjamin Travers, Surgeon to St. Thomas's Hospital, in 1824, said: "One of the great errors, it appears to me, in the treatment of inflammations of the eye has been the irritation of the organ by stimulant drops and ointments. I am satisfied many eyes have been thus destroyed." Writing of gonorrhea in 1675 the great Sydenham said: "He who cleanses well cures well." Mr. John Walker of Manchester, says in his "System of Ophthalmic Surgery," 1857, page 23, in speaking of the treatment of catarrhal ophthalmia: "I am in the habit of preferring the application of the nitrate of silver, or sulphate of copper in substance." In mild cases of the disease he says a single application of nitrate of silver will generally be sufficient, if followed by the frequent instillation of a solution of sulphate of zinc, or sulphate of copper.

Of the purulent conjunctivitis, three forms have been described, the mildest one being produced by the staphylococcus pyogenes albus. The next in point of severity is produced by the staphylococcus pyogenes aureus, and the most dreaded and malignant type by the gonococcus of Neisser. In the beginning period of the initial hyperemia the clinical characters are the same. The period of incubation, however, is different in each. Without treatment each of these forms of disease leads to results somewhat different. In each of them the tendency to produce papillary hypertrophy, formerly called granular lids, may be accounted about equal.

The white staphylococcus does not cause much tumefaction of the lids; it does not cause chemosis; it does not tend to produce corneal abrasions or necrosis until the stage of papillary hypertrophy of the palpebral portion of the membrane comes on. In the golden staphylococcus inflammation the lids are tumid from edema. The ferment invades the mucous follicles at the outset and swelling of the papillæ in the palpebral conjunctiva tends to cause corneal abrasions by the time the disease is a week old. In the white staphylococcus inflammation, on the other hand, the engorged papillæ are not notably present within a month from the beginning of the attack. In the gonorrheal infection the lids are enormously swollen and livid; abrasions of the conjunctiva lead to mingling of bloody serum with the earliest formation of pus. Chemosis of the conjunctiva is rarely absent. Without treatment the cornea undergoes sphacelation and sloughs within the first week. It is manifestly clear that the infecting ferment in the gonorrheal type not only takes possession of the mucous corpuscles and invades the follicles but likewise the surface epithelium of the interfollicular spaces.

It is well to remember that all the infectious or catarrhal types of conjunctivitis are retarded by the use of alkaline lotions, and that all are intensified and greatly aggravated by the use of stimulating astringents and caustic applications. The treatment by irrigation is the only rational mode of cleansing; it is easy of application, the means of applying it are universally accessible, and the results are all that could be desired.

In the white staphylococcus forms of infection the irrigation may be practised with normal salt solution, or with the following:

℞	Borate of sodium . . .	℥ iii
	Chlorid of sodium . . .	℥ ss
	Cryst. carbolic acid . . .	gr. xv.
	Water	gal. i.

The frequency of the irrigation should be regulated by the accumulation of matter on the surface of the conjunctiva. The upper lid being everted and the irrigating bag being hung twelve inches above the plane of the patient's eye the nozzle of the irrigator may be held over the bridge of the patient's nose and the fluid allowed to run over the everted lid and the inferior retrotarsal surface into a mass of absorbent cotton held on the temple. This should be repeated every half hour, and when the matter accumulates sufficiently to exude between the lids this interval should be shortened by one half. If no accumulation of matter appears the interval may be increased, say, first to one hour, then two hours, and so on until there is no necessity for the repetition of the irrigation.

In the yellow staphylococcus infection the treatment may be precisely the same; it will be found, however, that in some cases the irrigation must be repeated at intervals of ten minutes during a period of two or three days and nights. A week of assiduous devotion to this method of treatment could scarcely be compassed before complete recovery unless papillary hypertrophy had already set in.

In the gonorrheal type the same plan may be pursued, but a more efficient irrigation may be made by dissolving three ounces of chlorid of sodium, eight grains of bichlorid of mercury, and one-half dram of carbolic acid in one gallon of water, which should be filtered before using. With this the eye may be irrigated every ten minutes from the very beginning of the attack, and if the treatment is commenced before corneal or conjunctival abrasions occur it is well-nigh certain they will not occur afterward. There is always some danger in the case of infants, especially, of the cornea being injured by the nurse's finger-nails, and lest this accident should occur from contact with the nozzle of the irrigator great care should be taken never to allow the instrument to approach nearer than one inch. To perform the irrigation properly two persons are required. Having prepared the irrigation and placed the patient on his back one person may evert the lid and hold a mass of absorbent cotton wool on the temple to catch the outcoming discharge while the other manipulates the irrigator.

When it is known that more than twenty-five per cent. of all the blindness in the world has resulted from purulent conjunctivitis the importance of the most painstaking care in its treatment becomes apparent, and although it may seem a little formidable to have two nurses in constant attendance upon such a patient both day and night for a week or ten days the fearful consequences of neglect and the almost certain success which may be expected from the exercise of proper precautionary measures repays for trouble and expense. The great therapeutic indication in all cases of purulent conjunctivitis is set forth in Sydenham's declaration that, "He who cleanses well cures well." Frequent washing away of accumulated matter must terminate the course of the disease as soon as the whole contents of the invaded mucous follicles shall have been discharged. Since the more general adoption of this treatment of this class of diseases by irrigation, entropion, pannus, anterior staphyloma, and symblepharon are practically unknown; even opacities of the cornea are becoming comparatively rare from this cause. Blepharitis papillaris also is becoming comparatively rare.

Of the therapeutic agents now in most popular favor, in addition to those already mentioned, are nitrate of potassium in combination with hydrastis, formalin, 1 to 2000, or 1 to 4000. nitrate of silver, 1 to 2000 or 1 to 4000, corrosive sublimate, 1 to 1000 or 1 to 10,000, and a saturated solution of boric acid. The advocates of each of these methods of treatment by irrigation report vastly more satisfactory results than were obtainable by the old method of daily cauterization and the use of astringent collyria.

CLINICAL MEMORANDUM.

A CASE OF HERNIA OF THE PREGNANT UTERUS.

By W. V. ANDERSON, M.D.,
OF TOLEDO, OHIO.

TEXT-BOOKS on obstetrics make frequent mention of the fact that the abdominal walls may so yield to the pressure of the gravid uterus that the recti muscles will separate, allowing the uterus to carry the attenuated aponeurosis before it and thus form a hernia, the uterus being the herniated part; but nowhere, so far as I am aware, has it been referred to other than as an inconvenience and source of annoyance or pain to the pregnant woman, interfering with locomotion, etc. I think no one has mentioned this condition as a cause of dystocia and it is on account of this special feature that I present the report of this case to you to-day.

Reynolds, in speaking of the relaxation of the abdominal walls, says: "This is most likely to occur in women who have borne several children and usually only when the confinements have followed each other with considerable rapidity. It gives rise to the malposition known as anteversion of the pregnant uterus, in which the fundus may reach in extreme cases a position below the symphy-

[1] Read at the annual meeting of the Mississippi Valley Medical Association, held at Chicago, Ill., October 3–6, 1899.

sis, or may even rest upon the thighs, this displacement being rendered possible by the distention of the tendinous central raphe and overlying skin after separation of the recti muscles. It is productive of much fatigue and draging pain, but may be relieved by the application of the proper binder." Lusk says: "In extreme cases of pendulous abdomen, the uterus, having separated the recti, descends, covered by fascia and skin, almost or quite to the knees, and seriously interferes with locomotion. Its pressure also produces edema of the abdominal wall, vesical tenesmus, and pain in the distended cutaneous tissues. These symptoms are relieved by reposition of the uterus and by the application of a suitable abdominal bandage." In the experience of these or other writers the condition has not seemed to play any part in the mechanism of delivery. You will therefore probably be interested in my report, if not for its practical, at least for its historical value.

On the evening of March 9, 1894, I was called in consultation by Dr. Arne Zetlitz of our city, now of Sioux Falls, S. D. I found him in charge of a large, well-developed Polish woman, the mother of ten children. She had been in labor for thirty-six hours under the care of a midwife before Dr. Zetlitz was called. Upon examination we found that the abdominal muscles had been separated to such an extent that the uterus had passed out between the recti, carrying the aponeurosis in front of it and hung like a great pear suspended by its cervical attachments, the fundus reaching nearly to the knees. The uterus was freely movable and the os was fully dilated. The uterine contractions were good, considering the length of time the woman had been in labor, but the position of the uterus rendered them ineffective, for at each contraction of the uterus the patient would make vigorous effort to help herself, and though the uterus would rise until its long diameter stood at a right angle to the body, yet contraction and shortening of the abdominal muscles instead of assisting delivery, acted somewhat as a draw-string at the mouth of a pouch, so that the greater the voluntary effort the more it interfered with expulsion.

We placed her under chloroform, and after inverting the uterus and having it steadied by an assistant, Dr. Zetlitz attended to the anesthetic while I applied forceps (the head presenting O. L. A.) and delivered without difficulty a girl weighing seven or eight pounds. The birth canal was ample, and there was absolutely no cause of dystocia but the herniated uterus and consequent prohibitory effect of the contractions of the abdominal muscles. The second day after delivery Dr. Byron Robinson and Dr. Lucy Waite of Chicago being with us we invited them to see the patient. At that time the abdominal muscles were still so relaxed that they lay like rolls at either side of the abdomen giving it something of the appearance of a shallow bird's nest, with the recti muscles as the rim, the uterus covered by the loose flabby integument forming the bottom. The skin was so loose and the muscular roll so prominent that the fingers could be slipped under them and the muscles could be easily grasped as one can grasp the lapel of his coat. The woman made an uneventful recovery, and some three months later told me that she had no inconvenience following the delivery.

MEDICAL PROGRESS.

New Method of Treatment of Wounds.—SCHLEICH, in his book on the treatment of wounds which has just appeared, has attempted to simplify the methods of minor surgery so as to make the general practitioner independent of what he calls the monopolization and centralization of surgery. He disputes the assertion that bacteria are the chief source of infection. He looks upon them as the accompaniments of uncleanliness of which their presence is sufficient proof, but he rejects the idea that they are the cause of sepsis and pyemia for the reason that these diseases occur in the presence of very different forms of bacteria. He supports his ideas by the citation of other illustrations. For example, characteristic fevers follow the ingestion of spoiled meat and fish although under these circumstances only small numbers of the ordinary streptococci and staphylococci can be shown to be present. Schleich insists that the operator should disinfect himself immediately after contact with infectious material, so that at any time he may be looked upon as nearly aseptic. Hand-brushes he describes as universal labyrinths for grease and dirt. He rejects all sorts of chemical methods of purification partly because they do not destroy the bacteria and partly because they cannot be thoroughly carried out. He advises a mechanical cleansing calculated to wash away the bacteria. He uses a "marble soap" which is made of a special alkali (steral) and contains marble-dust to take the place of brushes. After the hands are washed they are smeared with wax-paste to close the ducts of the sweat- and fat-glands which no method is capable of disinfecting. In the treatment of wounds he has small regard for antiseptics which can only control to a limited extent the development of bacteria. He advocates an early and wide incision in suppurative processes and tamponade of the wound with gauze. He rejects all drains and uses silk instead of catgut, because he does not believe that the latter can be prefectly sterilized. He boils his silk and immerses it in gelatin to preserve it from infection. The gelatin is melted off with hot water at the time of use. He lays stress upon the necessity of introducing "homogeneous substances" between the edges of infected wounds. If this can be accomplished such wounds will heal in the same manner as healthy cut surfaces. Glutol, a dry and sterile formalin-gelatin, fulfils this requirement.

Another Method of Sterilizing Catgut.—FREDERICK (*La Gynecologie*, August, 1899) says that catgut can be sterilized and that a well-made knot will not slip; therefore the two objections to the use of this material do not hold good, while the disadvantages of a non-absorbable material are too evident to need further demonstration. He prefers formalin-catgut on account of the ease with which it can be sterilized in boiling water. The process of sterilization is a very simple one. The catgut is wound very tightly around glass plates in a single layer. The ends of the thread are caught in notches in the plate and securely fastened. This is to prevent the retraction of the gut which occurs if it lies loose in the formalin solution.

These glass plates are put in a jar containing a 3 per-cent. solution of formaldehyd in water. The commercial solution is a 40-per-cent. solution, therefore to obtain a 3-per-cent. solution it is only necessary to add to it thirteen parts of water. The solution will keep indefinitely and may be used over and over again. According to the size of the catgut, it is left in the solution from one to five hours. If left in too long it becomes hard and brittle. It is then removed from the formalin bath and placed in running water over night or for a time sufficiently long to remove every trace of formalin. Such catgut is not sterile but it is in a condition to be boiled in water without injury for a quarter of an hour. It is then preserved in sterile tubes which contain a mixture of glycerin which has been sterilized by boiling in a warm-bath and 95 per cent. alchohol—nine parts of alcohol to one part of glycerin. Such catgut is usually absorbed in eight or ten days. If it is desired to have a catgut which will last for several weeks, the glass plates with the catgut wound upon them are placed for twenty-four hours in a solution of bichromate of potash, 22 grains; glycerin and carbolic acid each 2.5 drams, and one quart of water. After twenty-four hours it is removed from the solution of bichromate of potash, washed and dried, and then placed in the formalin solution.

Purpura Hemorrhagica.—Williamson (*The Phys. and Surg.*, August, 1899) discusses the etiology of purpura hemorrhagica which was variable in the four cases cited. The first patient was a young lady apparently in perfect health who was badly frightened by an attack upon her escort in the evening. She received no physical injury but in a couple of hours she had a violent chill followed by hemorrhages from the nose, mouth, gums, kidneys, uterus, and bladder. A short time afterward ecchymoses came out simultaneously over nearly the whole body. The heart's action was very rapid—130 beats per minute. Nerve tonics, astringents, and iron tonic apparently arrested all bleeding, although for a long time any emotional disturbance caused a recurrence of epistaxis and bleeding from the gums. After a year's freedom from hemorrhages, marriage and a miscarriage caused a recurrence. Under tonic treatment she again improved and was well for two years until she gave birth to a full-term child. Then the hemorrhages recurred and soon after ended fatally. A second patient, a boy of three years, exhibited malaise, anorexia, and headache for two or three days, then multiple ecchymoses appeared in the skin of nearly the whole body. The child gained rapidly under treatment and was free from hemorrhages for four months. One day after vigorous play with an older brother he complained of feeling tired. Then came ecchymoses followed by vomiting, a comatose condition, and death forty-eight hours after the prodromal symptoms. In the third case mentioned the purpura was directly attributable to the administration of iodid of potash; while in the fourth case the outbreak of purpura happened in conjunction with pulmonary phthisis. Williamson considers the prognosis a grave one. His treatment is absolute rest in bed, liquid nourishment, and good hygienic surroundings. Ergot and other astringents have given him only negative results. Tonics of iron and arsenic he found to be the most satisfactory remedies.

A New Symptom of Obstructive Thrombosis of the Lateral Sinus.—Voss (*Arch. of Otol.*, August, 1899) believes that he has found a symptom which will enable one to make a diagnosis of thrombosis of the lateral sinus without a delay of three or four days. A normal unobstructed vessel, such as the internal jugular vein, gives a certain murmur which cannot be heard if the vessel is occluded. If the murmur is not present in a normal vessel it may be produced artificially by slight pressure of the stethoscope. A stethoscope is therefore placed lightly upon the neck close too the base of the skull. It is of advantage not to press too hard with the instrument. The stroke of the carotidis a guide and the pressure should not be sufficient to obliterate it. The ear must become accustomed to the loud tracheal râles. If the murmur is absent while present on the other side of the neck, or if light pressure upon the jugular fails to produce it, the inference is clear that the sinus is occluded by a thrombus. Owing to the entrance of the facial vein, the murmur may be present at the middle of the neck when absent higher up.

Do Patients Recover from General Peritonitis?—Stone (*Vir. Med. Semi-Month.*, September 8, 1899) says that most surgeons believe that the entire peritoneum is involved in conditions described as general peritonitis; but many cases tend to disprove this. The peritoneal cavity may be distended with pus, or blood, or bloody serum, without the existence of acute peritonitis either local or general. In some of these cases the pus is quite sterile; while in other instances, when the peritoneum is almost dry but very red, the patient may present grave symptoms of sepsis and shock. The severity of the disease must not be gaged by the mere presence or absence of fluid. Death may result when only a limited portion of the peritoneum is involved. Indeed, it is rare that a localized peritonitis becomes general, but without localization the process may rapidly spread over the whole peritoneum. As there are few, if any, recoveries from acute general pneumonitis when the entire lung surface of both sides is involved so there is every reason to believe that an inflammation of the whole peritoneum must usually prove fatal.

AN ADVANCE IN GASTRIC SURGERY.

The first meeting for the year of the Section on Surgery of the New York Academy of Medicine, an account of which may be found on page 574 of our present issue, brought out a series of clinical contributions, the results mainly of the summer's work, containing much that was of practical interest. Dr. Curtis's cases of pylorectomy and partial gastrectomy represent the newest phase of gastric surgery. How ultimately hopeless operations for gastric cancer are all surgeons are agreed. Even the recent cases of total, or almost total, excision of the stomach, which have attracted universal attention from their boldness, while successful as operations, have succeeded only in putting off the inevitable for a brief period. The step in advance then that is suggested by the proposal to operate before definite signs of cancer have presented themselves, promises to be a gain for surgery, provided certain reasonably sure indications for operative intervention can be established.

The proposal to resort to surgery in obstinate cases of dyspeptic trouble will not seem too radical to those who have realized the hopelessness of ordinary medical treatment in many of them. As was stated, French surgeons have not only argued very plausibly as to the advisability of surgical intervention in such cases, but have put the idea to the test with reported good results. Not only in stenotic conditions of the pylorus, but in dilatation of the stomach, and even in obstinate interference with its peristaltic functions, gastro-enterostomy is justifiable when it becomes evident that medical means will not give relief. The operation practically makes of the stomach only a very temporary receptacle for food, and dispenses with the gastric digestive functions entirely. Recent experiences, both medical and surgical, have shown, however, that the gastric functions are by no means the indispensable agents for digestion and nutrition that they have formerly been considered.

If by these operations for obstinate gastric dyspepsia the development of cancer of the stomach could sometimes be anticipated, as would undoubtedly be the case, for long-continued gastric irritation predisposes to cancer; or, as in Dr. Curtis's cases, if the cancer could, by a fortunate chance, be discovered before it had given rise to any characteristic symptoms of a malignant neoplasm, a most fortunate benefit would be secured for the patient and a great surgical triumph scored. The subject is yet in its incipiency, but enough has been done to point out a way of possible advance in surgery, in a matter that is of great practical importance, and which thus far has proved most discouraging.

SYPHILIS AND ITS INDIRECT EFFECTS UPON THE NERVOUS SYSTEM.

There are those who still refuse to admit the etiological connection between syphilis and such nervous diseases as locomotor ataxia and general paralysis of the insane. From year to year, however, their number is growing steadily less. Leyden's great influence remains constantly and consistently in opposition. He is the most prominent of those who refuse to accept the doctrine which the teaching of Erb and Gowers has made so universal. But the writings of his school only serve to keep from complete disintegration a cause that is every year losing in followers.

Two recent medical conferences have served to

bring out this fact with renewed emphasis. At the last meeting of the British Medical Association there was a discussion upon the relation between syphilis and general paralysis of the insane. Even the most conservative of those present conceded that while a certain impaired nervous constitution, either congenital or acquired by overwork or excess, is the favorite basis of the disease, syphilis is practically always its active cause.

Some of the recent statistics bearing upon the prevalence of the disease in certain places are of great interest. In Iceland previous to two years ago only three cases of general paralysis had been observed, one in a sailor, the other two in prostitutes who had relations with foreign seamen. In Ireland the disease is very rare. Among the Highlanders of Scotland it is extremely uncommon. Among the European peasantry it is infrequent, while in the cities of the European continent it is becoming increasingly more frequent. All of this points to its close relationship to syphilis which has the same variations in frequency. Of late a number of cases of adolescent general paralysis has been reported in patients between twelve and twenty years of age. Nearly every case gave evidence of congenital syphilis or at least presented suspicious circumstances.

At the recent International Conference for the Prevention of Syphilis and Venereal Disease, held at Brussels, one of the main reasons urged for the better regulation of venereal diseases and the spread of the knowledge of their baleful effects, more especially among the young, was this liability to post-syphilitic nervous complications. Dr. Jonathan Hutchinson of London, a most conservative thinker and writer, called attention to the fearful and hopeless affections of the spinal cord engendered by the disease, and while deploring extravagant sensationalism in the matter, said that we are bound to make the dread effects of the disease more widely known.

ECHOES AND NEWS.

Western Surgical and Gynecological Association. — The ninth annual meeting of this association will be held at Des Moines, Iowa, December 27 and 28, 1899. Surgeons and gynecologists of the great West are cordially invited to affiliate themselves with this association. George H. Simmons, 61 Market street, Chicago, is the Secretary and Treasurer.

Dysentery Epidemic in Japan —A special despatch to the *Chicago Record* from Tacoma, Washington, states that a terrible epidemic of dysentery is sweeping over Japan. Official statistics show, it is declared, that out of 50,000 persons attacked up to September 14th, nearly 12,000 have died. It is estimated that 100,000 cases will have been recorded before the end of October.

The New York Skin and Cancer Hospital.—The governors of the New York Skin and Cancer Hospital, Second avenue, corner of 19th street, announce that Dr. L. Duncan Bulkley will give a second series of clinical lectures on diseases of the skin in the out-patient hall of the hospital on Wednesday afternoons, commencing November 1, 1899, at 4.15 o'clock. The course will be free to the medical profession.

Obituary.—Dr. James Campbell, president of the Health Board of Hartford and one of Connecticut's most noted physicians, died October 17th, aged fifty-one years. He was graduated from the College of Physicians and Surgeons, New York. He became professor of obstetrics at Yale in 1866, and held that chair until last June. At the time of his death he was lecturer on Life Insurance at Yale, a chair which was created last year.

Utica Hospital Superintendency.—As the result of the civil-service examination held at Albany on October 16th for the appointment of a superintendent for the Utica State Hospital, the following candidates are eligible, ranking in the order named: Harold L. Palmer, State Hospital, Utica; Henry P. Frost, State Hospital, Buffalo; William L. Russell, State Hospital, Millard; Jelnin Courtney, Hudson State Hospital, Poughkeepsie.

The New York Obstetrical Society, Election of Officers. —At the annual meeting of the New York Obstetrical Society, held October 10, 1899, the following officers were elected for the ensuing year: Dr. Clement Cleveland, president; Dr. H. J. Boldt, first vice-president; Dr. R. Waldo, second vice-president; Dr. R. L. Dickinson, recording secretary; Dr. E. A. Tucker, assistant-secretary; Dr. E. E. Tull, corresponding secretary; Dr. J. Lee Morrill, treasurer.

The Death of Mr. William H. Appleton, the senior member of the firm of D. Appleton and Company, occurred at New York, October 19th. He was in the eighty-sixth year of his age. Although Mr. Appleton had not been active for some years past he was for many years one of the prominent factors in bringing American book-publishing to its present high level. To him is due the credit of giving noted impulse to the popularization of scientific facts and discoveries. In the medical world his firm is known more especially as the publishers of the *Popular Science Monthly*, the *American Gynæcological and Obstetrical Journal*, and our well known contemporary, the *New York Medical Journal*.

The Yellow-Fever Situation is in most particulars much improved. In the Gulf States generally, except Florida, the epidemic seems to be practically at an end. No new cases have been reported from New Orleans recently and quarantine

regulations against that city are no longer being enforced. New cases of the disease are still being reported at Key West but they are not so frequent as last week and the death-rate is very low. Unfortunately just as the disease seems about to die out at Key West a new focus has been lighted up farther north on the Florida Coast. An officer of the Marine Hospital Service who has been investigating suspicious cases at Miami, Fla., made public the following report on Monday of this week: "After a careful examination of many of the cases of fever, the State Health Officer announces the existence of yellow fever in this city. Five distinct cases of yellow fever have been seen, and from clinical histories submitted, there are doubtless several others. The infection is distributed over the town, mild in character, but unmistakable in recognition. To limit the spread of, and to destroy the infection as rapidly as possible, a depopulation of Miami is recommended." More cases are reported at Jackson, Miss.

Typhus on a Steamer.—Colonel J. Lewis Good, Chief of the Philadelphia Health Bureau, has taken prompt steps to avert any possibility of contagion from two cases of typhus fever which were discovered on board the Red Star Line steamer "Aragonia" when she reached that port on October 12th. One of the patients died on October 14th and the other is isolated and is likely to die. Thirty passengers on the "Aragonia" who were permitted to land before the true diagnosis was made, and who had scattered throughout the city, are now confined in two large tents on the grounds of the Municipal Hospital. The destinations of sixty other passengers, who were bound to different points in Pennsylvania, were learned from the books of the immigration inspectors, and the authorities of these towns warned to look out for their arrival. The New York State Board was notified on October 16th by the United States Commission of Immigration at Philadelphia that six of the "Aragonia's" passengers were bound for New York City and one for Binghampton. The names and residences of these people have been furnished so that the necessary precautions may be taken.

The Liverpool Malaria Commission Returns. — The steamer "Fantee" from Lagos has recently touched at Plymouth, England, with Major Ross and the other members of the Liverpool Malaria Commission on board. Dr. Ross speaks most hopefully of the prospects for complete extermination of *anopheles*. It has been found to be a shy and fastidious breeder, using only those pools and puddles which are permanent in character, whereas *culex* will breed in any rain puddle, barrel, or even sardine-tin which remains full of water for a few weeks. And as neither of these pests can breed successfully in pools or streams large enough to be stocked with minnows or into which fish can even penetrate at high-water, their larvæ being the favorite food of these useful little "shiners," the *anopheles* pools are both limited in number and can be picked out in any given area with comparative ease. Still another requisite must be present and that is a free growth of algæ, as the larvæ feed chiefly upon these in this intermediate stage of their development. By an interesting and, for everybody but the victim, most fortunate accident, one member of the party slept a single night without mosquito-curtains and promptly developed a sharp attack of malaria in consequence, while not another individual was attacked. This is confirmatory of the experience of Grassi as previously described in our columns. It will be remembered that Grassi, together with a young couple with five children, slept with open windows for eight nights during the dangerous season in the Roman Campagna, protecting themselves with fine mosquito-netting, and none of them was infected with malaria.

The Plague Situation is, on the whole, better than last week. For the third time now Alexandria is announced to be definitely rid of the plague. No new cases have occurred or at least none has been reported for over two weeks. It is to be hoped that the self congratulation of the Alexandrian sanitary authorities will not be rendered nugatory and a little ridiculous by the occurrence of further cases, as it has been twice already. At Oporto in Portugal new cases of plague still continue to occur each week. In general the situation there continues to be rather disquieting. Over 160 cases of the disease with 50 deaths have occurred up to the present time. We clip the following from the *British Medical Journal* with regard to the state of affairs in the Peninsula: "The Sanitary Commission has prohibited the holding of theatrical performances and public balls. This indicates a serious state of affairs, and it is unfortunate that the depressing influences of an epidemic are about to prevent means of amusement to a community. The sanitary officials have much to contend with in the face of the prejudice of the populace. Their beliefs indicate an Orientalism which, to those who do not know the Portuguese, will seem surprising. The people believe that the disease is the invention of the doctors, and that patients are taken to the hospitals only to be made away with. We look for such opinions in India and China, but scarcely believe it possible in Western Europe. The work even of the authorities is not carried on with that degree of enlightenment one would expect. One example will suffice. In a low part of the town of Oporto a boy died of plague. Policemen were stationed at the street door of the house and at the door communicating with the flat in which the boy died to prevent the inmates, to the number of nine, coming out. There these people were incarcerated in a manner worthy of medieval times. To those who know Portugal these reports are not surprising. Orientalism tinges many of their beliefs and customs, and, seeing that three-fifths of the nation are wholly illiterate, one is quite prepared for outbursts of an almost fanatical nature. Even Dr. Jorge, the enlightened medical officer in charge of the plague, summed up his opinion of the state of certain quarters of the town as "*une ville Orientale.*" The opinion of Dr. Calmette is that the number of plague cases is much more considerable than the official statistics indicate. The majority of the poorer classes never send for a doctor, and many prefer to die rather than enter a hospital. The proportion of fatal cases to those attacked is satisfactorily small. This hopeful state of things may be due to the

use of the serum prepared at the Pasteur Institute, which, according to all reports, is efficacious both for preventing and curing attacks of plague, when rightly employed." In India the situation is practically unchanged. In the Presidency of Bombay as a whole, the disease is rather worse than better and the usual winter recrudescence of plague seems just beginning. At Poona, however, the improvement noted last week and the week before continues and there is hope now that the disease is definitely under control. Lord Curzon, the Viceroy of India, and his staff are about to visit the plague-stricken districts. An attempt is to be made, by having the Viceroy and his immediate following publicly inoculated with protective serum, to convince the natives of its harmlessness and get rid of the prejudices against it. The British Government in India seems to be waking up at last to the necessity incumbent on it of taking every possible means in its power to stamp out the disease. The Viceroy's visit is meant to wake up local governments to a proper sense of their duty in the matter. From the China Coast there are no more alarming reports. At Mauritius the situation remains about the same. At Lorenzo Marques, in Portuguese South Africa, plague undoubtedly exists. Since the breaking out of the Boer-English war, the town is fairly overrun with refugees. Thousands of people are huddled together in cramped quarters. There is a large representation of natives, roughs from the gold fields and Malays and Indians imported to South Africa to work in the gold mines. Law and order is at an end, and it is feared that the plague will work havoc in the town owing to the impossibility of enforcing sanitary regulations.

MEDICAL MATTERS IN NEW YORK.

DEATH OF DR. HENRY J. KELLY—PHYSICAL EDUCATION SCORED—NEW BINOCULAR MICROSCOPE—TYPHOID IN BROOKLYN—LOVE AND DUTY SUCCESSFULLY COMBINED — A PLUCKY SURGEON—DAMAGES IN AN ACCIDENT CASE—A CONSUMMATION DEVOUTLY TO BE WISHED—ST. LUKE'S HOSPITAL WORK—LOOMIS LABORATORY SUIT.

Dr. Henry Joseph Kelly died on October 16th. He was graduated from the College of Physicians and Surgeons, was a New York Hospital Interne, and had practised for eighteen years in this city. He was forty-two years old. He was a member of the Medico-Legal and the County Medical Societies, and of many other associations. He had served most acceptably for the past ten years as instructor in bandaging at the New York Polyclinic.

The condition of physical education in the public and private schools of this city was the subject of adverse comment at the meeting of the Physical Education Society of New York and Vicinity, held on October 19th. Dr. Walter L. Savage considers that the new public schools in the city are highly satisfactory to upholders of physical education in one way, but a great disappointment in another. They are all well equipped with gymnasia and gymnastic apparatus, but these are not used. Moreover, the system which regulates physical education in the public schools is wrong. Two supervisors are supposed to give instruction to about 6000 teachers, a manifest impossibility.

At the New York Microscopical Society's twentieth annual exhibition on the evening of October 20th, Dr. Carl Zeiss' recently invented binocular microscope was the most interesting feature. It is the first of its kind seen in America. Its two tubes do not converge, but are parallel. The effect is to bring out the object under inspection in plain perspective, and to make all the dimensions clearly visible.

The prevalence of typhoid fever in the neighborhood of Keap and South Third streets, Williamsburg, caused residents in that vicinity to hold an indignation meeting on the evening of October 21st. Committees were appointed to protest to the Health Department against the lack of sewer facilities and the dirty streets, and to obtain signatures to a protest. The mortality has of late been on the increase, and the streets have not been so filthy in many years as they now are.

Dr. R. W. Plummer, a surgeon attached to the Marine Hospital at the Brooklyn Navy Yard, found himself recently in a distressing situation. He was assigned to the cruiser "New Orleans," which sailed October 21st for Manila. On the other hand, he was engaged to be married some time this winter to a young lady living in Dayton, Ohio. As soon as he received his assignment he telegraphed his affianced to come to the Brooklyn Navy Yard to bid him good-bye. On her arrival on October 19th an idea suddenly evolved itself from somewhere among the subliminal strata of Dr. Plummer's consciousness. This was to suggest that they be married at once, and on board ship. The prospective Mrs. Plummer agreeing, the ceremony was performed by Chaplain Curtis H. Dickens of the cruiser "Chicago," which vessel, no doubt by a special dispensation of providence, was lying near by. Among the wedding party were Rear-Admiral Philip and Captain Longnecker of the "New Orleans." We heartily regret to announce that the "New Orleans" sailed for Manila on October 21st, two days after the wedding.

A Bellevue Hospital ambulance, while hastening in response to an emergency call, was badly wrecked by being caught between a truck and a trolley-car. Glass flew in all directions from the broken windows of the car, the driver was forcibly thrown to the ground and badly cut and bruised, while the ambulance surgeon was violently knocked about in the ambulance, being bruised and cut by the flying glass. Without thought for himself, however, he sought the nearest telephone, announced the catastrophe to Bellevue Hospital, and asked that another ambulance be sent to the point of his destination. With the blood still trickling from a scalp wound, he boarded a truck standing near, and was driven to his "call." When he arrived at the hospital with his patient, it was found that the surgeon had an injured left ankle, a bruised forearm, a swelled head, and several minor cuts and bruises, but the patient was safe and comfortable. This is in striking contrast to the action of the ambulance surgeons who, when summoned recently to care for victims of an accident on the Brooklyn Elevated, spent their time

wrangling over their respective claims to the sufferers while the latter writhed in agony.

Mrs. Thora Scott recovered judgment for damages on the trial of her suit against Charles Banks, in this city, for an injury which she received by falling into a coal-hole in front of the latter's premises. The Appellate Court, however, directed a reversal on the principle that where actual pecuniary damages are sought some evidence must be given showing their existence and extent. Two physicians had been treating Mrs. Scott for a considerable period, but no evidence was given as to the value of their services. The court said: "As it is impossible to say how much the jury awarded for the services of these physicians, and how much for the plaintiff's pain and suffering, the verdict cannot stand."

Chief Inspector Martin of the Division of Food Inspection, Offensive Trades, and Mercantile Establishments of the Health Department declares that the Barren Island nuisances no longer exists. Dr. Martin made an inspection of Barren Island affairs last spring, acting under orders from the Health Board, and the recommendations he then made touching improvements in the various rendering plants on the island have been complied with, so it is said. The inspector has himself made a weekly inspection, and two deputies have gone over the various works each day, as a result of which the objectionable features have been eliminated. For many years the foul odors from this island have been the despair of the inhabitants in the vicinity. Governor Roosevelt has appointed a special commission to investigate the plant.

The annual meeting of the Society of St. Luke's Hospital was held at the hospital October 17th. The annual report was read. During the year ending September 30, 1899, 2703 patients were treated. Of these 507 paid full rates, 334 paid part rates, and 1862 were non-paying. The total expenses for the year were $167,910.53. There was a deficit in current expenses of $68,648.30. Gifts and donations were received by the hospital for the endowment amounting to $227,750.

A suit has been brought by the New York University Medical School against the Cornell Medical School to compel the latter to grant the students of the former school the privileges of the Loomis laboratory. This suit was brought before Justice Truax of the Supreme Court on October 20th. George A. Strong, Esq., counsel for the New York University School, based the rights of his client in a great degree on the following statement of Dr. Alfred L. Loomis, recorded in the minutes of a meeting in the spring of 1887:

"About one year ago a gentleman gave me a power of attorney to spend $100,000 for him in the erection and equipment of a laboratory building for the exclusive use of the faculty and students of the medical department of the New York University. He designated that it should be known as the Loomis Laboratory of the Medical Department of the New York University; that, when completed, it should be handed over to a board of trustees, which should hold it for the use of the faculty and the students, as already indicated; that in everyway, as might from time to time be indicated by the faculty, it should be used to increase the teaching facilities of the medical department of the university; that if at any time the council of the university shall assume the pecuniary obligations of the faculty and take the college building, the trustees of the laboratory may transfer the laboratory property to the council. In accordance with the wishes of the donor I have had a bill introduced in the Legislature, incorporating the laboratory, with the following board of trustees, viz., D. Willis James, F. L. Stetson, C. E. Miller, A. L. Loomis, and H. P. Loomis. The two last names were insisted on by the donor. . . .

"The donor will give the faculty any legal documents which they may wish, guaranteeing to them that the laboratory and its equipment shall always be for their use in laboratory teaching. It is understood that the trustees are to be simply the custodians of the property and of any endowment which the laboratory may receive."

Mr. Willis H. Paine was the donor referred to. Among other things the plaintiff cited that the laboratory building bears upon the front, carved in stone, in letters a foot long, the name of New York University, placed there by Dr. Alfred L. Loomis, who gave an endowment to the laboratory amounting to $25,000. Charles E. Miller, Esq., counsel for the Cornell School, stated that the Loomis Laboratory denied there ever was any such trust as the one alleged, and that the property was conveyed to the defendant for the promotion of original research in chemistry, biology and pathology, and for elementary teaching in those branches, under such regulations as the board of trustees should, from time to time establish; that it has always been so used, according to chapter 329, laws of 1887, under which it was incorporated.

In 1897 there came a split in the medical faculty of the New York University, many of its members going to Cornell. A majority of the governing faculty went to Cornell, and for two years the Loomis Laboratory has been used for Cornell students. New York University has tried to obtain the use of the building, but could not do so; hence the suit.

Justice Truax was prepared to decide at once, but at the request of plaintiff's counsel he reserved decision for three weeks in order to give counsel time to submit briefs.

The Health Department submits the following report of contagious diseases for the week ending October 21, 1899: Measles, 140 cases and 3 deaths; diphtheria, 188 cases and 29 deaths; laryngeal diphtheria (croup), 8 cases and 5 deaths; scarlet fever, 116 cases and 6 deaths; smallpox, 3 cases and 0 deaths; chicken-pox, 19 cases; tuberculosis, 179 cases and 134 deaths; typhoid fever, 72 cases and 22 deaths; cerebrospinal meningitis, 2 deaths. Total, 725 cases and 201 deaths.

Insurance against Illness.—Nearly 8,000,000 persons in Germany belong to the Krankenkassen, or, in other words, are insured against illness. One-third of these reported illness in 1898, the average duration being seventeen days, which, taking the average of wages at only fifty cents a day means a loss of nearly $24,000,000 a year.

MEDICAL MATTERS IN PHILADELPHIA.

AN ATTEMPT TO EXTEND THE PRIVILEGES IN POST-MORTEM STUDIES—FRESH OUTBREAK OF SMALLPOX—THE PHILADELPHIA PATHOLOGICAL SOCIETY, ELECTION OF OFFICERS—THE DIAGNOSTIC VALUE OF GALL-STONE CREPITUS—GLANDULAR INVOLVEMENT IN SCARLET FEVER—THE QUESTION OF PUBLIC-SCHOOL FILTERS—THE SALARIES OF DISTRICT PHYSICIANS—HEALTH REPORT.

PHILADELPHIA, October 23, 1899.

THE attempts which are now being made by the more progressive members of the Board of Charities and Corrections, the governing body of the Philadelphia Hospital, to secure for the benefit of medical students more extended privileges in post-mortem studies in this institution, are being vigorously opposed by certain other members of the Board who believe that the medical student-body should be denied the proposed opportunities for practical instruction in pathological histology. Such opposition is traditional at Blockley, and the gentlemen who are at present renewing the fight for the medical student are simply rehearsing ancient points of contention, but with, let us trust, more tangible hopes for the success of their efforts than have been obtained by their predecessors. Dr. Joseph S. Neff, who represents the progressive element of the Board, contends for the adoption of a resolution permitting the attending pathologist of the hospital to utilize the pathological specimens at that institution and to make autopsies for the purpose of instruction, suggesting that a committee of pathologists be appointed to select appropriate pathological specimens for demonstration, with, as in the past, the invariable rule that permission of the deceased patient's family is obtained in every instance before the post-mortem examination is held. The contention of other members of the Board is that the benefits to be derived from the study of morbid specimens should be confined to members of the hospital's medical staff. Unfortunately, from the present complexion of affairs, the friends of the medical student appear to be still in the minority, and the extramural use of pathological material at Blockley must continue to remain a proscribed privilege.

The preparations recently made by the health authorities to cope with the predicted outbreak of smallpox this fall have already been called into service. During the past week the expected outbreak occurred, and from a single house eleven persons, half of whom were affected with the disease, were removed to the isolation wards of the Municipal Hospital. No fear is entertained that the outbreak will spread, for appropriate measures were at once put in force to stamp out the pest, and to prevent its dissemination in the neighborhood.

At the last meeting of the Philadelphia Pathological Society, held October 12th, the following officers for the ensuing year were elected: President, Dr. Frederick A. Packard; vice-presidents, Drs. Joseph McFarland, Charles W. Burr, Alfred Stengel, and W. M. L. Coplin; secretary, Dr. J. Dutton Steele; treasurer, Dr. Thompson S. Westcott; recorder, Dr. David Riesman; curator, Dr. W. Wayne Babcock. Committee on Morbid Growths, Drs. W. S. Robertson, David Riesman, and Thomes S. Kirkbride, Jr. Committee on Membership, Drs. Alfred Hand, A. O. J. Kelly, and Joseph H. Jobson. Committee on Publication, Drs. Alfred Stengel, A. A. Eshner, and Joseph McFarland. Business Committee, Drs. A. C. Abbott, Joseph Sailer, David L. Edsall, John M. Swan, and H. R. M. Landis. The annual address before the Society was delivered by the retiring president, Dr. W. E. Hughes.

The diagnostic value of gall-stone crepitus and friction was the chief subject of discussion at the last meeting of the Philadelphia County Medical Society, held October 11th. Dr. J. M. Anders, who presented a paper upon this topic, argued the value of this sign, especially in cases of cholelithiasis in which, from the absence of all clinical signs save perhaps jaundice, due to obstruction of the common duct by a gall stone, the diagnosis was often extremely difficult. In such instances, the speaker maintained, in spite of the absence of other clinical symptoms, the condition might be frequently recognized by detecting, either by simple palpation or by ausculatory palpation, a quite evident friction and crepitus over the site of the lesion. Dr. Mordecai Price mentioned the occurrence of a somewhat similar crepitant sign produced by the rubbing together of the enlarged glands in carcinoma; and Dr. S. Solis Cohen summed up the value of the signs, as aids in the recognition of cases presenting atypical clinical symptoms, which, if diagnosed at an early period, may often be treated with success.

The glandular involvement in scarlet fever was the subject of a series of investigations recently completed by Dr. J. F. Schamberg, the results of his study being presented at the last meeting of the Philadelphia Pediatric Society, on October 10th. Dr. Schamberg found, from the study of 100 cases of scarlet fever, that the various lymphatic structures were affected in the following percentages: inguinal glands, 100 per cent.; axillary glands, 96 per cent.; maxillary glands, 95 per cent.; anterior cervical glands, 44 per cent.; submaxillary glands, 36 per cent.; epitrochlear glands, 26 per cent.; and sublingual glands, 25 per cent. No definite diagnostic value could be attached to the conclusions reached by the speaker, save for the fact that in most cases of erythematous eruptions associated with diphtheria the glandular involvement was much less widespread.

The question of public-school filters is apparently dead and buried, in spite of the elaborate tests made of these instruments, the flowery promises of the Councilmen entrusted with their selection, and the $75,000 appropriation available for their purchase and introduction. Councils' committee and the Board of Education being involved in the throes of a heated and entirely hopeless discussion over certain trifling technicalities of the question, the subject seems quite hopeless of solution. Meanwhile the schools have again opened for the winter session, and the pupils must perforce imbibe Schuylkill water in virgin turbidity—until general filtration of the water-supply of the whole town becomes an established fact.

A committee representing the fifty District Physicians of this city has recently presented an argument to the authorities asking for an increase of salary, which at present amounts to the munificent sum of $20 per month. The committee contends that District Physicians are the poorest paid employees connected with any municipal department, and that, at their present rate of pay, their average fee for each visit does not amount to more than ten cents. This, they claim, is highly unjust, and request that a salary of $60 per month be allowed to each physician engaged in district charity practice under the regulations of the City Board of Charities.

The total number of deaths in this city for the week was 384, or an increase of 2 over the number reported last week, and a decrease of 5 from the corresponding week of last year.

ANNOUNCEMENT.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

PARIS, 2D TO 9TH OF AUGUST, 1900.

THE American Committee of the Thirteenth International Medical Congress met at the University Club, Philadelphia, October 21st, at 3 P.M., at the call of Dr. William Osler. Present: Dr. W. W. Keen, president of the American Medical Association (in the Chair); Dr. George M. Sternberg, Surgeon-General of the United States Army; Dr. Wm. K. Van Reypen, Surgeon-General of the United States Navy; Dr. Walter Wyman, Surgeon-General of the United States Marine Hospital Service; Dr. Horace G. Miller, president of the American Otological Society; Dr. E. D. Fisher, president of the American Neurological Association; Dr. George J. Engelmann, president of the American Gynecological Society; Dr. H. W. Stelwagon, president of the American Dermatological Association; Dr. Samuel Johnston, president of the American Laryngological Association; Dr. R. F. Weir, president of the American Surgical Association; Dr. A. Jacobi, president of the American Climatological Association; Dr. E. G. Janeway, president of the Association of American Physicians, and Dr. Henry Koplik, president of the American Pediatric Society.

Letters of regret at inability to attend the meeting were reported from Dr. H. P. Bowditch, president of the Congress of American Physicians and Surgeons (absent in Europe); Dr. O. F. Wadsworth, president of the American Ophthalmological Society; Dr. James Bell, president of the American Association of Genito-Urinary Surgeons; Dr. H. M. Sherman, president of the American Orthopedic Association; Dr. R. H. Chittenden, president of the American Physiological Society; Dr. B. G. Wilder, president of the Association of American Anatomists, and Dr. B. Holly Smith, president of the American Dental Association.

Dr. Osler stated that in May he had received instructions from the Secretary of the Congress in Paris to organize the American National Committee. After consultation with Dr. W. W. Keen, the President of the American Medical Association, and Dr. H. P. Bowditch, the President of the Congress of American Physicians and Surgeons, he had nominated as members of the Committee the Presidents of the American Medical Association, of the Congress of American Physicians and Surgeons, and of the constituent societies composing the same, the Surgeon-General of the Army, of the Navy, and of the Marine Hospital Service, and, at Dr. Keen's suggestion, the President of the American Dental Association. Dr. Sternberg moved, seconded by Dr. R. F. Weir, that the American Committee of the XIII. International Medical Congress consist of the gentlemen just named. Carried.

Dr. Osler then read the following letter which he has received from Dr. Chauffard, the General Secretary:

"Honored Colleague: I have the honor to state that I have sent you—(1.) A package of subscription blanks ("Forms of Adhesion"). (2.) Some account books with stubs. Please insist that your fellow-countrymen conform to all the directions which are therein contained.

"Pray distribute, together with our subscription blanks, announcements of your own, indicating the name and address of the representative of your committee to whom the subscribers in your country should address the subscription blanks when filled, as well as the corresponding funds. It is then understood that these blanks constitute simply a sort of propaganda, and that we shall consider as members of the Congress only those gentlemen who shall have sent to your committee the amount of their subscription, and shall have received in exchange the receipt from your account book (leaflet C). . . ."

It will thus be seen that the work of each National Committee of this Congress is very different from that heretofore intrusted to them. Physicians in this country who wish to become members of the Congress must apply to the Secretary of the National Committee, who will forward a blank of application, which is to be filled in and returned to the Secretary, with a fee of five dollars.

Dr. Janeway moved, seconded by Dr. Wyman, that Dr. Osler be empowered to appoint a physician as Secretary to the Committee, and to secure such aid as would be required to carry on the work. The question of meeting the expenses of the Committee was left to the Chairman. If each National Committee is expected to meet its own expenses it was agreed either to call upon the Treasurers of the Societies represented in the Committee, or upon the individual members. It was moved by Dr. Engelmann, seconded by Dr. Stelwagon, that the medical journals of the country be requested to aid in making known as widely as possible the conditions under which registration in the Congress may be effected.

Dr. Osler announced that he would nominate Dr. Henry Barton Jacobs, 3 West Franklin street, Baltimore, Md., as Secretary of the Committee, to whom all applications for blanks should be sent.

While it is to be understood that the Central Committee wishes the subscriptions to be sent to the Secretary of the National Committee, Rule 3 of the Congress provides that persons wishing to be members may forward their subscriptions to the Treasurer-General of the Congress.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

TYPHOID IN THE DUBLIN POLICE-BARRACKS—ELECTRIC LIGHT FROM DUST—SALT-FISH POISONING—ELECTRIC BATHS IN LEAD-POISONING—FATAL MISTAKE BETWEEN BOTTLES—A NEW VARIETY OF TRAINED NURSE—HYPNOSIS BY THE X-RAYS—INCREASE OF VACCINATIONS UNDER THE CONSCIENCE CLAUSE—TUBERCULOSIS AMONG ENGLISH DAIRY COWS—OPENING AT THE LONDON POLYCLINIC—A CELEBRATED MEDICINE MAN—NORMAN KERR'S SUCCESSOR.

London, October 15, 1899.

There appears to be little question that the typhoid fever, the outbreaks of which are becoming a chronic scandal in Dublin, and which has just spread to the police barracks and numbered several constables among its victims, is due to an infected milk-supply. The attention of the Nationalist City Council has been repeatedly called to the fact and its cause, but as any active interference with the notorious filthiness of the dairies would certainly seriously offend their good friends and supporters, the milkmen, and incidentally uncover other troubles, municipal uncleanliness besides, they decline, Tammany-like, to do anything in the premises.

Anything which makes sanitation and municipal cleanliness easier and less expensive is of the highest value. Now that sewage-farms have made the liquid waste of a great city an actual source of income, it only remains to attack the problem of the dry refuse, technically known as "dust," but consisting largely of paper, straw, packing-materials, packing-boxes, husks, etc., which accumulate at such an appalling rate in the streets and yards of a great city. The annual report of the electric-light plant at Shoreditch Vestry calls attention in the most striking manner to a solution of this problem. Two years ago the Vestry inaugurated an electric-light service, using as motive power the heat from its dust destructors and furnaces. Success at that time appeared too good to be true, but the first year was unexpectedly favored with a surplus of income of nearly ten thousand dollars, and that this was no flash in the pan has been proved by the result of the second year with a credit balance of nearly twenty-seven thousand dollars, and this has been accomplished solely by the destruction of no less than 23,000 tons of refuse. Now that it has proved a success, the surplus is to be applied very properly to the reduction of rates to the consumers of the light. Really as wonderful things are made out of the dust of the earth nowadays as of old in the Garden of Eden. It is to be hoped that the brilliant example of Shoreditch Vestry will be widely followed.

A most curious case of poisoning has been reported from Liverpool. In one neighborhood no less than five working women died suddenly with symptoms of food-poisoning within a few days of each other, and upon investigation it was found that all the deceased had dined one day on salt fish and potatoes at a stall in St. Martin's Market. A bacteriological examination of the bodies by Professor Stewart of University College, revealed the fact that the poisoning was due not to ready-found ptomains, but to the introduction of a bacillus. This is rapidly coming to be regarded as the actual state of affairs in most cases of so-called meat-poisoning, sausage poisoning, and so forth. The bacillus belonging to the typhoid group and closely resembling what has long been known in the laboratories as the "rabbit septicemia organism," usually produces its effect with great rapidity, but may exhibit an almost typical typhoid course, which accounts for the disputes and perplexities which have arisen over various cases of meat poisoning, as to whether the disease were a half intoxication or merely an outbreak of typhoid, as in the celebrated case at Sabina, Iowa, in which forty or fifty guests at a wedding banquet who had partaken of a chicken salad were attacked by what seemed to be in many cases typical typhoid, so that this claim was actually set up as part of the defence in the numerous damage suits that were brought.

Public attention is being called to the most encouraging results obtained by baths and other forms of electric treatment in the case of victims of lead-poisoning, of which so much has been heard of late. One establishment in Wolverhampton has attained a great celebrity throughout the pottery district in this respect, and no less than thirty-one cases of this distressing condition have been treated there in the past four months. Of these, twenty-four patients are said to have been cured and five others remarkably improved, so that with this and the prospect of reformatory legislation the workingmen in this dangerous trade are beginning to feel much more cheerful about their prospects.

It appears that our supposition as to the cause of the poisoning of Dr. Dick by his own medicine, reported in our last letter, was not supported by the evidence given at the inquest, in so far as a repetition of an intended dose of the alkaloid was concerned. The unfortunate man stated before his death that he had not put a particle of strychnin into the medicine, the only colorless fluid which he had used being, as he alleged, a mixture of chloroform. As the mixture contained an abundance of strychnin, and no chloroform whatever, the mystery was only solved upon going to the dispensing shelves in his surgery and finding there two bottles of colorless solution one above the other, the upper containing chloroform water and the lower strychnin. Obviously one bottle had been picked up in mistake for the other, and although both were labeled, the lower did not have a poison label or mark upon it, an omission which we fear is all too common in the case of similar poisonous solutions on our own shelves. Had it been so labeled, there is a possibility that it might have caught his eye and the mistake been avoided, although unfortunately the mistake would still have been easily possible, as some of us can testify through painful experience or narrow escapes. The recommendation of the Coroner's Jury in commenting on this unfortunate omission, however, ought to be promptly heeded and acted upon both by the profession and the legislators, and that is that all poisonous solu-

tions should be kept in deeply fluted bottles. One may fail to look at the bottle which he is using, but he must touch it in order to do any harm with it, and if this touch alone will report upon or remind you of its nature, mistakes will be almost impossible.

An excellent scheme which will command the cordial approval of all members of our profession has just been set on foot by the ladies of the Sanitary Association of Liverpool. This is the formal training of young women of refinement and education for the care of young children. The need and value of such a class of nurses is too obvious to need comment. Hitherto there has been a serious gap between the trained obstetric nurse of the first few months and the hospital trained nurse only available in case of sickness or invalidism. Intelligent, scientific, and above all refined care and oversight of the details of the life of young children has a value which can hardly be overestimated. The new nurses are to be trained in the proper making and fitting of children's hygienic clothes, the sanitation of the nursery, the principles of feeding, and also in the elements of the kindergarten system. A similar institution was organized at Norwood in London a couple of years ago, and has met with great success.

The field of women as hospital physicians is steadily widening. Week before last the Hospital board of Govan, a district of Glasgow, appointed Miss Augusta Boyes, M.D., Ch.B., as resident physician to its Fever Hospital, at the same time raising the salary attached to the appointment. Last week the Edinburgh Victoria Hospital for Consumptives also appointed a lady, Dr. Anne Mercer Watson, as resident physician.

Another unexpected effect of a "bye-product" of the X-rays has just been reported by Mr. Harrison Low in a demonstration at the London Polyclinic, namely, a production of hypnosis, especially in young children. He found in two cases in children and one in an adult that by the time the skiagraph had been taken they were in a nearly comatose condition, having shallow respiration, dilated pupils, and pallid skin; in fact the first patient was in such a curious state and required so much rousing that he was quite alarmed until he recognized the true nature of the condition. In all of the three cases it occurred while the patients were lying upon their backs on the photographic table, having a picture of the hips or knee-joints taken, and of course, gazing with the eyes in a somewhat strained position steadily at the eery, rapidly alternating, greenish flicker of a Crookes' tube would furnish ideal conditions for the production of hypnosis.

The vaccination movement is going steadily forward in spite of opposition and risky conscience clauses. Indeed, the latter appears to have even almost improved the situation, as the report of the first six months under it shows an excess of nearly 75,000 vaccinations over a similar period in the previous year. The antis, robbed of their battle-cry of tyranny and oppression, and pretty well discredited on vivisection grounds by the rapidly growing public appreciation of the value of the results of animal experimentation in diphtheria and consumption, are now desperately hunting a new war-cry, and as Mr. Chaplin has finally issued a mandamus to compel the Leicester Board of Guardians to appoint a Vaccination Officer, they think they have here found what they need in the shape of a side issue on "interference with local self-government" by the central authority. While it might have been more judicious on Mr. Chaplin's part to avoid treading upon the tail of the coat so ostentatiously trailed upon the ground before him by the pugnacious Guardians, yet as the matter stands he could hardly avoid taking action and the mind of the public will appreciate the real issue, in spite of the clouds of "local-government" dust which may be raised to obscure it.

The Health Congress at Blackpool, which recently closed its sessions, was in no way remarkable from any point of view. In fact, to the professional eye its proceedings seemed tame and trite, but then of course, the dear public likes and needs elementary pabulum to feed its interest in these subjects. Probably the nearest approach to anything new was the statement of Professor Penberthy of the Royal Veterinary College, London, that 30 per cent. of English dairy-cows are tuberculous, a statement which, though startling, is we fear, supported by all the data available, including the testing of milk-samples for bacilli, carried out by Kanthack just before his death, and Delepine's later experiments, showing their presence in 15 per cent. and 20 per cent. of the samples respectively. But it is far from proven as yet that even such bacilli-laden milk is infectious to man, although this fact is usually taken for granted.

The October term of the London Polyclinic opened with a fair enrolment of students and members. These latter now number more than 500. Clinical demonstrations will be held every afternoon during the winter, and American and Colonial members of the profession are cordially invited to visit these during their stay in London.

Members of our profession sometimes obtain an unexpected celebrity in other fields, and a case in point is the "American Hercules" now exhibiting in London as a champion "strong man" and rival to Sandow. He is said to be a graduate of Harvard Medical College, and to have been in actual practice two years, but left it for a more lucrative and fame-bringing occupation. He claims to be a grandson of Sitting Bull, the renowned Sioux Medicine Chief, so that he is of the profession by blood as well as by education.

The Society for the Promotion of the Study of Inebriety has just filled the vacancy left by the death of their famous president and founder, Dr. Norman Kerr, by the election of Dr. Wynn Westcott.

A most absurd and exasperating instance of "Justices' justice" was recently afforded in Southwark. Samples of ice-cream were seized on suspicion of injuriousness and submitted to analysis. The Public Analyst at London, Dr. Stevenson, a scientist of world-wide reputation, reported them to be swarming with bacilli, among them the bacillus coli communis. Suit was brought but upon the counsel for the defense eliciting from Dr. Stevenson that the examination had not been made by him personally but by his bacteriological assistant, Dr. Parks, the local Dogberry refused to receive his certificate as evidence!

TRANSACTIONS OF FOREIGN SOCIETIES.

THIRD INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

RELATIVE VALUE OF ANTISEPTICS AND TECHNIC IN PRODUCING GOOD RESULTS AFTER OPERATION—TREATMENT OF UTERINE RETRODEVIATIONS—HYSTERECTOMY FOR FIBROMATA — COMPARISON OF CÆSARIAN OPERATION, SYMPHYSIOTOMY, CRANIOTOMY AND PREMATURELY INDUCED LABOR—TREATMENT OF UTERINE CANCER—REMOVAL OF THE UTERUS IN CASE OF DOUBLE ADNEXAL SUPPURATION—TREATMENT OF GYNECOLOGICAL FISTULÆ—PREVENTION OF ASPHYXIA DURING LABOR.

THE Third International Congress devoted to gynecology and obstetrics was held at Amsterdam, August 8th to 12th. The first paper was read by RICHELOT of Paris, on the relative value of antisepsis and technic in securing perfect operative results. He said that to rely upon antisepsis is a mistake because even the best antiseptics are insufficient to prevent either primary or secondary infection. Furthermore, antiseptics are dangerous in that they interfere with the union of wounds, while producing cellular necrosis, they prepare the way for points of infection. Of the sterilization of instruments and materials used he had only good words to say, but he emphasized the difficulty of its perfect accomplishment. Finally, one has to place his reliance upon the power of Nature to heal, hence the importance of employing the best technic. One should reject every instrument which is useless. Dexterity, ingenuity, and judgment are the qualities which make for success. Gynecological methods of procedure have been simplified and the results have been proportionately improved. Any one of the major pelvic operations may be taken as an illustration of this point. for example, hysterectomy. A still further advance in technic will give a new impulse to conservative gynecology by enabling the operator to substitute for the extirpation of organs, therapeutic measures more delicate but equally successful in removing the cause of the trouble.

HEINRICIUS of Helsingfors opened a discussion on the treatment of uterine retrodeviations. As retrodeviations almost always co-exist with inflammatory troubles, it seemed to him natural to think that the symptoms under these circumstances are due to a chronic inflammation in the form of metritis, perimetritis, etc., rather than to the abnormal position of the uterus. Consequently he looked upon treatment directed solely to correction of the displacement as absolutely useless.

ZIEGENSPECK of Munich said that a false position of the uterus alone, by twisting of the vessels, is quite capable of accentuating the difficulties due to an abnormal pelvic circulation. It can also increase the risk of infection.

GOLDSPOHN of Chicago denied that intervention to remedy false positions of the uterus is a useless procedure. In cases in which uterine retroversion of a non-infectious character is complicated by pelvic adhesions, he finds it necessary besides shortening the round ligaments to enlarge the internal inguinal ring with the fingers or a dilator and through this opening to free the uterus from its pelvic adhesions. If the adnexa are diseased he draws them out through the inguinal opening and performs whatever operation may be indicated. This accomplished the inguinal canal is closed with four layers of sutures, the second of which is made to include the round ligament, which is fastened to the posterior side of the femoral arch. Operating in this manner he has had more than 150 cures, one-third of which were confirmed by examination of the patient more than eighteen months after operation.

DOYEN of Paris said that phlebitis, albuminuria, intestinal obstruction, and malignant degeneration of the fibromatous uterus, so far from being contraindications for operative treatment, rather render immediate operation absolutely necessary. It is rarely of service to remove an isolated myoma either by the vagina or by laparotomy. When multiple fibromata are present, vaginal hysterectomy is indicated, if the uterus is easily movable, and especially if the vagina is large or if the patient is so stout that a laparotomy may be difficult. Under other circumstances the abdominal operation is preferable. Since Doyen has employed the ecraseur and has substituted ligatures for clamps, he has performed fifty two hysterectomies for fibroma. The vaginal operation was performed upon twenty-seven patients, all of whom recovered; while of the remaining twenty-five patients on whom abdominal hysterectomy was performed one died.

BALDY of Philadelphia expressed himself in favor of supravaginal amputation of the uterus and suture of the peritoneum over the stump, without abdominal drainage. This method is applicable in all cases. Preservation of the cervix is an advantage in that it reduces the chances of infection and preserves the normal shape of the vagina.

JACOBS of Brussels said that hysterectomy for fibroids is contraindicated in the presence of extreme anemia, Bright's disease, degeneration of the tumors, with serious changes in the abdominal viscera, and carcinoma of the cervix. The mortality after abdominal hysterectomy as performed by him is three per cent. His practice is to amputate supravaginally and then to remove the cervix except in certain instances in which the cervix is normal. Hemorrhage is controlled by an electrical apparatus.

ALEXANDER of Paris said that total hysterectomy is unnecessary if a fibroma is of less than two-pounds' weight. Enucleation of a fibroma is a far less formidable operation than hysterectomy, and it should especially be performed if the patient is young. He has enucleated as many as twenty-five fibromata at one time. Doubtless some fibromatous nodules remain under such circumstances, but he has never observed a recurrence of the trouble. At any rate it is better to run the risk of recurrence a second and even a third time than to remove the uterus.

TREUB of Amsterdam thinks that the treatment of fibromata by injections of ergotin and electricity is too generally neglected. By these means he has obtained a certain number of incontrovertible successes in cases in which the tumors were of moderate size, soft, and did not give rise to hemorrhage.

PINARD of Paris compared the Cæsarian operation,

symphysiotomy, craniotomy, and prematurely induced labor. He inclines toward the Cæsarian operation with suture of the uterus and abdominal wall, rather than to hysterectomy. Symphysiotomy was practised 100 times in the Beaudelocque Clinic from 1892 to 1899. There was a mortality among the mothers of 12 per cent. and among the children of 13 per cent. Twenty-two of the mothers again became pregnant and six of them were a second and even a third time subjected to the operation, while the other sixteen gave birth spontaneously. Eighty-one craniotomies occurred in the speaker's service from 1882 to 1899 producing a maternal mortality of 11 per cent. A comparison of the best statistics shows that after prematurely induced labor the infant mortality is about 30 per cent. and that of the mothers is 2 per cent. or less. These results should assist the obstetrician in deciding the proper measure to be carried out in any particular case. The opinion is universal, however, that if the contraction of the pelvis is extreme Cæsarian section should be performed. Such cases are rare. When there is a moderate amount of pelvic contraction symphysiotomy is preferable to Cæsarian section.

Reynier of Paris in discussing the treatment of uterine cancer said that vaginal hysterectomy is being laid aside for the operation by the abdominal route. By the latter method one can determine the exact extent of the tumor, and can operate successfully in cases in which it would be unjustifiable to operate by the vaginal route. Even when the lesions are plainly of a limited extent, abdominal hysterectomy facilitates the complete emptying of the pelvis which is just as indispensable to the cure of cancer in this locality as is the clearing out of the axilla in cancer of the breast.

Jacobs of Brussels said that the abdominal operation is the only one which should be performed in the treatment of cancer of the uterus. During the past eighteen months he operated upon twenty-three patients, twenty-two of whom recovered from the operation, while up to the time of report no recurrence was evident.

Janvrin of New York gives preference to the vaginal operation, but he refuses to operate unless the disease is limited to the cervix or to the fundus or to the endometrium. In the operations performed by him from 1883 to 1896 in accordance with these principles he was able to obtain thirty-three successes in 100 cases.

Hartmann of Paris said that patients whose adnexa have been removed for double suppurative troubles find themselves much improved, but, nevertheless, after exertion suffer from pain in the lower part of the abdomen, renal difficulty, leucorrhea, and occasionally from hemorrhage. Examination under these circumstances shows a persistent metritis with small indurated nodules in the pedicles. To complete the cure extirpation of the uterus is necessary. The vessels in the pedicles should be ligated separately, and the peritoneal wounds stitched together to restore the pelvic floor. If possible one ovary should be left to save the patient from the troubles due to a premature menopause.

Faure of Paris expressed himself in favor of the abdominal route in chronic adnexal suppuration as permitting the surgeon to perform a more accurate and complete operation. In certain acute or subacute cases in which the pus has a particular virulence, vaginal hysterectomy is preferable as less likely to result in peritonitis.

Doyen of Paris spoke of gynecological fistulæ which he divided into those occurring spontaneously and those resulting from operation. The former are due to labor, obstetrical operations, pelvic suppuration, and the presence of some foreign body in the uterus or bladder. For fistulæ of the bladder or ureter he has never found it necessary to perform a laparotomy. This is the proper operation in cases of intestinal fistula whether it opens into the bladder or through the skin or into the vagina. In Trendelenburg's position the fistula should be dissected, the intestinal coil freed, withdrawn, and the opening into it closed with Lembert sutures.

Rapin of Lausanne said that asphyxia of the infant during delivery may be prevented by the introduction of air into the uterine cavity by means of a metallic or a soft rubber catheter. The air injected should be sterilized, and the quantity should not exceed in most cases 600 c.c. Gaseous embolism is not to be feared, for the air does not enter the uterine cavity but the amniotic cavity.

SOCIETY PROCEEDINGS

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 5, 1899.

The President Dr. William H. Thomson in the Chair.

The paper of the evening was read by Dr. Virgil P. Gibney, and was entitled

CERTAIN ASPECTS OF BONE AND JOINT DISEASE OF INTEREST TO THE GENERAL PRACTITIONER (see page 545).

In discussing the paper Dr. Abram Jacobi asked the author if he had understood him to say that sarcomata sometimes occur which do not fluctuate. Dr. Gibney replied that localized points of fluctuation are the most characteristic physical signs of sarcomata. Dr. Jacob said that a sensation of at least semi-fluctuation is pathognomonic of sarcomata. Ordinary fluctuation occurs, of course, in cystic sarcomata and in mixed tumors containing cysts even though they be small ones, but this semi-fluctuation occurs even in sarcomata that are not in the least cystic. With regard to the confounding of scurvy with joint or bone lesions, it is not at all uncommon. There are two affections occurring in children for which scurvy is particularly mistaken: acute rheumatism, and acute anterior poliomyelitis. There is practically no reason at all why scurvy should be confounded with the latter disease. There is, of course, absence of movement in the limbs in both cases, but in anterior poliomyelitis this is due to inability to move them because of palsy. In scurvy the failure of movement is due to pain. This can very easily be decided by passive movements. The mistaking of scurvy for acute rheumatism is a little more justifiable and the two conditions are not so easy to dif-

ferentiate. In scurvy, however, the hemorrhage is not into the joint and not into the epiphysis, but practically always into the diaphysis of the long bones. It is true blood extravasations occur at times over the tissues and occasionally even over the carpus, but these are rare exceptions. If the bones are protected from motion it will be found that the joints in scurvy may be freely moved. It is true, that at times in scurvy hemorrhage occurs into the joints, and this may almost hopelessly confound the disease with rheumatism, but these joint hemorrhages are very rare. In his last fifty cases of scurvy the speaker had seen but three.

Rachitis is very important as a source of bone and joint disease because of the deformities it produces in these structures, but still more so because of the deformity of all the internal organs that it gives rise to. There is scarcely a single internal organ that does not suffer. The heart and lungs are especially interfered with. In the scoliosis of rachitis the lungs are greatly crowded, their arteries are interfered with, and their nutrition impaired, so that rachitic children suffer for this reason a good deal from bronchitis and other pulmonary affections. The aorta is often distorted and in severe scoliosis may be quite bent upon itself by the pressure of the lungs. The heart itself is more exposed in the triangular rachitic chest than in the normal elliptical thorax; less of it is covered by lung anteriorly and it is more pressed against the anterior thoracic wall. It seems as a consequence of this to be hypertrophied. It gives a larger area of dulness and a more diffuse and forcible apex beat than the normal heart, but the hypertrophy is apparent not real.

It must be borne in mind, however, that not only the intrathoracic organs suffer and become deformed in rickets but that the abdominal organs are also affected. The lack of room in the thorax leads to the crowding down of the liver and spleen. Their circulation is interfered with, their nutrition lowered and they are left much less capable of resisting toxic and infectious agents of all kinds. The liver is pressed down upon the stomach and the functions of that organ seriously hampered. The kidneys are displaced and the interference with their circulation and the malnutrition induced by pressure leads to nephritis. It is very important to have a knowledge of these changes, not so much in order to be able to recognize them after they have occurred as to prevent their occurrence. After all rickets is perfectly amenable to treatment at the beginning. This should not be delayed until a serious condition has developed but should be begun early in the affection. Even slight forms of rickets may give rise to serious organic deformity.

Dr. Joseph D. Bryant said that in all cases of trauma the condition of the patient at the time of the occurrence is of the utmost importance. A slight injury may in states of lowered resistive vitality be followed by serious consequences. It has often been remarked that slight injuries are apt to have more serious after consequences than severe ones. Something of this is due to the care that is bestowed upon the severer forms of injury. Even the slightest injuries occurring in people in delicate health should be most carefully treated.

With regard to sarcomata of bone it is almost marvelous how often they are taken for something else. In this matter the relation of slight injury to the after development of sarcoma as pointed out by Coley should be borne in mind. It may occur after very slight injury but may follow severe injury. In a recent case a man of seventy-nine hurt the anterior femoral surface in rising from a table. For some time the muscles were sore. This passed off completely. About four or five weeks afterward there was a recurrence of pain which was thought now to be due to rheumatism and was treated as such. Some relief seemed to be afforded by hydrotherapic treatment at watering-places and later by electrical treatment. After four months, however, the tumor had become the most prominent symptom. One night in turning over in bed a fracture of the femur occurred. It was considered to be due only to the ordinary senile tendency to fracture and was treated simply as such. When finally a consultation was held there was marked fluctuation all over it and yet the true condition of sarcoma was unsuspected. Whenever swelling occurs without inflammatory symptoms a neoplasm should be suspected. It must be remembered that in sarcomata a local increase of temperature is not unusual and slight constitutional febrile movements also occur.

Rheumatism is the affection that is diagnosticated in many of these cases that later prove to be either malignant or tubercular, so that a good deal of hesitation should be the rule in making the diagnosis of rheumatism unless there are some characteristic symptoms. On the other hand it must not be forgotten that the inactivity necessitated after trauma during treatment sometimes predisposes to rheumatic affections.

Necrosis of bone often develops after seemingly inadequate causes. The speaker had seen three cases of necrosis at the lower posterior part of the femur, which somehow were the result of trauma at that site and the patients could scarcely be sure of the cause. In all of these the diagnosis had been rheumatism. Even after the occurrence of abscess this diagnosis was persisted in and in one case the opening of the abscess had led to puncture of the popliteal artery and a fatal termination. These necrotic conditions are evidently worth looking for carefully when there are obscure conditions in the popliteal region.

In affections of the hip-joint, though the fact is so constantly pointed out, it is still forgotten that the pains are apt to be referred to the knee. Here is where the diagnosis of rheumatism and of growing pains are especially liable to be the refuge of the careless physician. Absolutely nothing can be found at the joint itself, hence the tentative diagnosis. In general whenever the nerves to to any part pass over a joint before they reach the part in which the pain exists, it is important to examine the joint in question carefully before coming to any diagnostic conclusion as to the cause and source of the pain. This rule will often be of great service in tubercular cases, especially in obscure affections of the spine. In these cases pain is often referred to the epigastrium or other parts of the abdomen.

Dr. Charles N. Dowd said that, struck by the num-

ber of cases of serious bone and joint disease the diagnosis of which had been mistakenly made as sprain or rheumatism and the treatment for these affections applied, he had collected the statistics of some recent cases at St. Francis' Hospital. Out of ten cases of tuberculosis of the ankle-joint, seven were considered sprains when the first symptoms appeared and the history of an injury was considered the main feature of the case, though careful inquiry elicited the fact that some symptoms existed prior to the injury. Out of ten cases of tubercular knee-joint an equal number, seven, were set down at first as sprains. In like manner four out of ten cases of tubercular hip-joint disease were at first thought to be traumatic cases. In spinal tuberculosis this element was not so prominent. Rheumatism had been the original diagnosis in some of the other cases. Rheumatism is rare in young children, however, and there is very little excuse for mistakes of diagnosis. The diagnosis of sprain is more justifiable, but when in a young person after the lapse of months and the employment of reasonable care there still remain symptoms, or perhaps the condition has grown worse in the meantime, it is time to think that some other condition than sprain is present.

Even when the diagnosis of a tubercular affection is made very early in the case it is practically almost impossible to get patients or have their friends allow them to undergo the proper treatment for a sufficient length of time. The same thing is true of pulmonary tubercular affections. Patients get some better under the influence of change of climate, diet, and drugs and then they want to return to work at their old homes and to former habits. A relapse is almost inevitable and the only thing for the physician to do is to represent to patients and their friends all the gravity of the situation at the very beginning, and have them understand that the only hope of permanent cure is the most sedulous care in following the directions given for a long period of time.

As a comment on Dr. Gibney's two cases of hematoma in the gluteal region Dr. Dowd had a case to report in which a tumor developed in the gluteal region shortly after trauma. On removal one pathologist said it was a sarcoma, another thought not. Though the operation wound remained absolutely uninfected a serous discharge persisted for some weeks after the operation, which in the speaker's experience is characteristic of sarcomata. This tumor seemed to be one of those dubious fibrosarcomata in which the line between inflammatory fibrous tissue and neoplastic connective tissue is not exactly drawn.

Dr. John B. Walker said that there would appear to be a special joint lesion, the true significance of which is so often missed that it seems to deserve a special mention. These are the so-called sprains of the knee in which the semilunar cartilage is displaced. This displacement is liable to recur unless the condition is recognized and treated properly by rest and position on its original occurrence. A point of tenderness with some prominence may often be found anteriorly or slightly to the side of the knee just above the upper end of the tibia. This is the displaced cartilage itself and it may be pressed back into position.

Dr. S. A. Knopf called attention to the greater frequency of tuberculosis among children than is usually imagined, and the consequent necessity for being on the watch for tubercular bone and joint disease in them. Neumann of Berlin lately found in investigating the cases of 135 boys and 130 girls who were hindered from going to school that 14 of the boys and 15 of the girls had scrofula or some other tubercular affection. The speaker asked Dr. Gibney what his experience with the Beers treatment had been. Beers, and after him others, recommended the application of a wide rubber band just above the affected joint tight enough to affect the venous and not the arterial circulation. The production of venous congestion in the tissues leads, it is claimed, to increased leucocytosis and the presence of more CO_2 than usual. These factors inhibit the growth of tubercle bacilli and finally destroy them. The treatment of tubercular bone and joint diseases in children is most successfully carried out at seaside sanatoria. German, and especially French and Italian experience shows this. We have very few such institutions in this country as yet, but we must have them soon.

Dr. A. H. Smith said that a feature of bone and joint disease of great interest to the general practitioner is the occurrence of lesions in these structures after typhoid fever. Typhoid spine is well known. Recently during a typhoid case he noted a symmetrical subperiosteal enlargement on the crest of both tibias. In both, abscess occurred with slight exfoliation of bone. In another very similar case suppuration occurred only on one side; hot applications caused resolution without pus formation on the other side. In a very recent case of symmetrical typhoid swellings on the tibia in a young lady suppuration seemed to be prevented by hot applications. The fact that injury so often precedes the development of sarcoma is becoming more and more clear, and should not any longer lead to a wrong diagnosis of these neoplastic tumors.

Dr. H. E. Gallant said that melanotic sarcomata are especially liable to fluctuate. There are two tumors that deserve careful differentiation from them: hematomata of which the contents have been partly absorbed, and lipomata. Both of these may fluctuate. One of the reasons why tuberculous joint affections are treated so often as sprains, is that they so often originate in sprains or rather in the mistaken notion of treating them that is so prevalent. It is the custom to immobilize sprained joints. This leaves the effused fibrinous material which is exuded at the time of the injury, the chance at least to partially organize and so make recovery longer and less complete. In this imperfectly formed tissue of low vitality, micro-organisms find a favorable nidus for growth and this proves a frequent origin of tuberculous processes. After an interval of immobilization of the joint we proceed to break up the adhesions that our method of treatment has allowed to form. Why not rather prevent their formation by passive motion and massage shortly after the accident? On the second day after a sprain or even earlier these measures may be employed and will give great relief from pain and restore

function. An hour after the accident the pain may be so much lessened that a patient can walk comfortably.

DR. GIBNEY in concluding the discussion said that prompt treatment of rickets so as to forestall deformity would be much more satisfactory to the surgeon than to have to correct the deformity it entails. As to the importance of sprains as occasions for the development of tubercular joint affections the case would seem to be rather the reverse; the awkwardness induced by the tubercular process very early in the affection causes a tendency to these injuries. This is one reason why they seem to occur so often and one excuse for the mistake in diagnosis at first. The subluxation of the semilunar cartilages of the knee is an important condition that should be recognized and treated carefully, for it seems to bear a causal relation to the subsequent occurrence of tubercular arthritis of the knee-joint. As to the Beers treatment of arthritis by venous congestion he had never had very much confidence in it. He would prefer to produce anemia rather than congestion. Sanatoria by the seaside are, of course, ideal. We have found, however, that if the children can only get away from the city into the country anywhere, into the mountains or into a farming country, it greatly aids their convalescence.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON SURGERY.

Regular Monthly Meeting, Held October 9, 1899.

THE Chairman of the Section, DR. CHARLES N. DOWD, in the Chair.

The meeting was occupied with the presentation of patients showing the results of operations performed, mainly during the summer months.

DR. B. FARQUHAR CURTIS presented

TWO CASES OF RESECTION OF THE STOMACH.

The main interest of the cases was that, in both, the tumors seemed to be benign before the operation, but proved on removal to be carcinomatous. They open up the question of the possibility of very early operations for carcinoma ventriculi, *i.e.*, at a time when the neoplasm is just becoming cancerous. The first case was that of a man, aged twenty-eight years, whose mother had suffered a great deal from stomach trouble. He had had all the diseases of childhood and also smallpox. He had never had syphilis nor rheumatism. He was the purser of a steamboat, and once while on a trip to Africa had an attack of bush fever, otherwise he had always been in good health, until about five years ago when the trouble began that finally brought him to the hospital for treatment. At first he noticed distress after eating and a capricious appetite. At times he did not care at all for food, and at others ate voraciously. His discomfort was relieved by the belching of gas. After a year of this he began to vomit, at first two or three times a week so that a week never passed without at least his vomiting once. Then he began to vomit practically every day, and finally even oftener. Sometimes he noted in the vomited material substances that he had eaten two or three days before. He never vomited blood nor coffee-ground material. When he came to the hospital for eighteen months he had been using the stomach tube regularly and washing out his stomach. This afforded him relief at first but later had seemed to do very little good. He lost more than fifty pounds in weight and on entrance to the hospital tipped the scale at 108 pounds.

Examination showed that the stomach walls were thickened, and that there was a tumorous mass in the right hypochondrium. The tumor was neither tender nor painful. On its surface two nodules could be felt. The stomach was considerably dilated, and held about fifty ounces of water. The free hydrochloric acid was lessened in amount, and also the total acidity. Starch digestion was very little impaired. There was slight fermentation in stomach contents that had been retained for some time. With this condition operation was advised and accepted. It was thought that a benign stricture of the pylorus would be found.

A vertical median incision was made from the tip of the ensiform downward for about three inches, and the tumor was found to consist, as had been supposed, of a thickened pylorus. There were no adhesions, but two enlarged glands were found along the lesser curvature of the stomach. An incision was made about an inch from the tumor, the stomach walls being carefully held in apposition by an assistant. Only a small incision was made at first, and the edges of the stomach carefully sewed together as far as the incision went. Then the cutting was done once more, followed by suturing as before. In this way there was very little, if any, danger of extravasation of stomach contents. The stomach was closed up completely along its cut edge by this method, and a double tier of Lembert sutures used to secure perfect closure. The cut end of the duodenum below the tumor was then fitted with a Murphy button, the other portion of which was inserted into the stomach wall posteriorly. This is Kocher's method of performing gastro-enterostomy except for the employment of the Murphy button.

The recovery from the operation, which lasted about an hour and a half, was very satisfactory. The pulse was never above 126; the temperature never above 101.5° F. He required but very little stimulation. Rectal feeding was continued for three days, only the presence of an irritable hemorrhoid making this method of giving nourishment very unsatisfactory. Then feeding by the mouth was begun, and was kept up without inconvenience.

Thirteen days after the operation the patient had gained twelve pounds, while thirty days after he had gained twenty-eight pounds. He has continued in good health, though he still has some dyspeptic symptoms. He cannot eat meat, and he occasionally suffers from vomiting. There has not been time as yet for contraction at the site of insertion of the Murphy button, so that it seems not improbable that the opening out of the stomach is somewhat smaller than it should be. Adhesions as the result of the operation may also be a cause for a disturbance of stomach function.

The next case was somewhat similar. The patient was a German woman, twenty-eight years of age, with a nega-

tive family history. She had not had any of the diseases of childhood. She was operated upon about four years ago for some gynecological lesion. Afterward she had a child and some time later began to experience some discomfort in the right hypochondriac region. There was a pulling feeling causing so much gastric discomfort that she sometimes tickled her throat to make herself vomit. When she vomited the matter brought up was sometimes streaked with blood. She grew worse and lost her appetite completely. A tumor developed in the epigastric region and she lost in weight. When she entered the hospital there was a tumor half the size of the fist just above the umbilicus. It was hard to the feel, tender and painful. It was a smooth rather flat tumor without nodules. It did not move with respiration and was adherent to the abdominal walls.

There was a question as to whether it was not originally a tumor of the abdominal walls that had become adherent to the underlying organs. There were certain suspicious cicatricial marks around the nose that recalled syphilis and suggested the possibility of a gumma of the rectus muscle. The pain and tenderness suggested ulcer and the thought was confirmed by the presence of adhesions. On the other hand, nothing in the history would confirm the diagnosis of ulcer.

At the operation the rectus muscle was found infiltrated and the peritoneum beneath it was thickened. Beneath this the stomach walls were very much thickened, at least to an inch in cross section, while a large tumor existed near the pylorus. There was a hard gland on the lesser curvature not far from the tumor. An ulcer of the stomach wall was found in the region occupied by the tumor. The stomach was dilated and about two-thirds of the dilated organ was removed, leaving a stomach about half the normal size. This was closed and a gastro-enterostomy by Kocher's method with the use of the Murphy button was performed just as in the preceding case.

The operation occupied more than two hours and the patient was considerably shocked. Her temperature rose to 105.2° F. These high temperatures during the first few hours after the operation, careful observation has shown recently to be indicative of shock. The patient was treated by stimulants and intravenous injections of saline solution. This brought the temperature down. On the next day it rose to 103° F. and did not rise again to any significant degree. In this case rectal feeding was kept up for ten days, very differently from the procedure in the first case in which mouth-feeding was resumed on the third day after the operation. She was not hungry for three weeks and for nearly two weeks could scarcely be induced to take food. Some pus formed within the abdomen but as the wound had been closed hurriedly with simple through and through sutures it was easy to secure its evacuation.

The patient had not been weighed before the operation. On the thirty-second day after the operation she weighed 87 pounds and on the fifty-sixth day 105 pounds. She is naturally of very feeble constitution. She now has much less discomfort and more desire for food than at any time for many months.

Examination of the specimen disclosed the fact that the tumor was a carcinoma and this was confirmed by the fact that the glands removed were also carcinomatous. The specimen in the first case was also pronounced carcinoma, though unfortunately the glands removed were not examined. It seemed clear that the case was one of simple hypertrophic stenosis of the pylorus and the glands when cut into seemed enlarged from simple inflammatory irritation. The degeneration into carcinoma could only have occurred quite recently for it is too much to assume that for the five years the symptoms were in existence there had been a cancer of the stomach present.

Dr. Coley said in discussion that his experience demonstrates the usefulness of the Murphy button in these cases. Recently he had had occasion to perform a lateral intestinal anastomosis. He had closed both ends of the gut and had employed an oblong Murphy button.

Dr. Charles N. Dowd said that the ultimate results of the operations for exsection of portions of the stomach were sufficiently encouraging to make the operation more frequent. The actual specimens from a case were shown at a German medical congress recently, in which though considerably more than half the stomach had been removed by operation, the organ removed at the autopsy was practically of normal size. The stomach seems to have very great powers of regeneration and of accommodation to the new circumstances of dilatation.

Dr. Curtis in conclusion said that he considers Kocher's method of gastro-enterostomy (as he had employed it) better than lateral anastomosis. With regard to the two cases presented he thought they justify the conclusion that there is a field for surgical operations on the stomach before cancer declares itself unmistakably. There is undoubtedly, as French surgeons have shown, an opportunity for surgical intervention in cases of persistent digestive disturbances. A gastro-enterostomy has been suggested, and has in a number of reported cases given relief from symptoms.

Dr. Walker said that Dr. Weir has adopted the French suggestion of gastro-enterostomy for these severe chronic dyspeptic cases recently and has been very well satisfied with the results obtained.

Dr. John F. Erdmann presented a case of

Ileus Cured by Operation by Simple Untwisting of the Intestine.

The patient, a man of forty-eight, came to the hospital with a pulse of 145, and a temperature of 102.5° F. The abdomen was tense, but contained no localized tumor. An incision was made through the left rectus muscle below the umbilicus, and was afterward extended across above the umbilicus into the right rectus muscle. The sigmoid presented in the wound. It was four inches in diameter and the dilatation extended up as far as the xiphoid and over into the right hypochondrium. A twist of fully 180° was found in one of the loops and this was untwisted, and as the mesentery was very long was secured by sutures so that it could not retwist. Recovery was most satisfactory. There was no temperature

above 100° F. at any time. In a few days the patient was able to eat heartily. He was able to be about after two weeks, and after six weeks he resumed his occupation of shoemaker. This requires a good deal of bending forward with effort yet the scar shows not the slightest sign of yielding. The patient does not wear a bandage and is perfectly comfortable in every way.

In discussion DR. FARQUHAR CURTIS said that he preferred to have patients after laparotomy wear a belt. The case was very different from a hernia. In hernia the intestine forces its way into a small opening and pressure from without does not prevent it from doing this. In the case of a ventral scar, however, the object is to prevent the scar tissue from stretching, and so allowing the intestines to push out. An abdominal belt could prevent this by absolutely relieving the abdominal wall of all pressure.

DR. COLEY agreed with Dr. Curtis as to the desirability and usefulness of a belt after abdominal operations. It certainly does relieve many symptoms of which patients complain.

DR. BOLTON presented a case of

SUTURE OF FRACTURED PATELLA WITH PERFECT RESULT.

The knee-joint was opened and evacuated of blood and serum two days after the accident, and finally washed out with normal salt solution. The ends of the aponeurosis of the rectus muscle were then sutured together, and the cartilage below the patella. The man can now, three years after the operation, go up and down stairs as well as ever.

DR. CURTIS said that it was recently demonstrated to him that the prognosis after suture of the patella in these cases cannot be sure. He sutured a patella, and after six months it was refractured by a sudden effort of the patient to keep himself erect in a cable-car. He sutured it once more, this time with wire. The wire tore through, for within a year it was fractured again, and again sutured. Each time there was bony crepitus and union seemed to have been good.

DR. CHARLES N. DOWD presented cases of

TUBERCULAR ENLARGEMENT OF INGUINAL GLANDS.

In both cases the patients, boys of eight and ten years of age, had tuberculous sores on the legs or feet. In one the popliteal glands broke down. In the other a sore on the foot seemed tuberculous in character. In both cases the glands were removed. The chain of glands had to be followed, because of recurrences, in along the iliac vessels, and the wound packed.

DR. COLEY presented photographs of two herniæ of the umbilical cord. In one, the size of a small orange, the edges of the abdominal opening were freshened and brought together, and a good result secured. In the other practically all of the abdominal organs were in the hernial sac, very little abdominal wall tissue existed, and nothing could be done. This patient, though the mother was living in the tenement-house district, was alive three weeks after when inquired about, though usually the little patients die before this. Cases of hernia of the umbilical cord are very rare, yet both these patients came to the Hospital for Ruptured and Crippled within a single week.

THERAPEUTIC HINTS.

Swabbing with Carbolic Acid in Pertussis.—GUIDA of Naples employs this means of treatment with very favorable results as to the evolution of the disease, and recommends certain modifications of the usual procedure. He has the throat swabbed at the time of the attacks, instead of in the intervals, thereby avoiding the induction of another fit of coughing. It is also easier to accomplish in the case of very young children than when they are quiet. He uses a stronger solution than that generally accepted as suitable. In case of children under one year the following formula is given:

℞	Ac. carbolici cryst. . . .	gr. xxiv
	Glycerini pur.	ʒ iiss
	Syr. tolutani	*m.* lxxx.

M. Sig. Local use.

In the case of children over three years of age, when it is possible, as a rule, to swab the throat more extensively and longer at a time, the solution is weaker and contains cocain:

℞	Ac. carbolici cryst. . . .	gr. xvi
	Glycerini	℥ ss
	Sol. cocainæ hydrochlor. two per cent.	*m.* lxxx.

M. Sig. Local use.

Guida states that the treatment has always been well tolerated by his patients.

Care of Mouth, Throat, and Nose in Typhoid Fever.—The nasal cavities and mouth should be washed out regularly and carefully with a weak solution of boric acid. If the patient is able to gargle the following may be used to advantage:

℞	Salol	gr. lxxx
	Tinct. benzoinæ . . .	gtt. xxx
	Spts. menthæ piper . . .	℥ viii.

M. Sig. One teaspoonful in a glass of water as a gargle.

Cleanse the tongue and gums frequently by means of a bit of absorbent cotton held in forceps and wet with boroglycerin (ten per cent.). Introduce several drops of menthol-vaselin (five per cent.) or boric-vaselin (ten per cent.) into each nostril.—*Lyon.*

For Exophthalmic Goiter.—VETLESEN of Christiania, influenced by the belief that mineral acids act as tonics to vasomotor nerves, has tried their effect in the above-named disease, and reports excellent results in a number of cases. He prescribes ten drops of dilute sulphuric acid three times a day.

For Syphilitic Coryza in Infants.—

℞	Hydrargyri chlor. mit. . .	parts i
	Vaselini } aa.	parts v.
	Lanolini }	

M. Ft. unguentum. Sig. For swabbing the nasal passages.

ORIGINAL ARTICLES.

MOUNTAIN FEVER.[1]

BY E. STUVER, M.D.,
OF FORT COLLINS, COL.

MOUNTAIN FEVER is a subject that has caused a great deal of contention and led to many heated discussions in the medical profession. On the one hand it is claimed that in pathology and symptomatology it is merely typhoid fever modified by the climatic and local conditions of the region in which it is found. On the other hand it is just as strenuously asserted that it is a disease entity entirely distinct from typhoid fever. These wordy, and at times, bitter and acrimonious discussions are, in my opinion, largely due to the lack of a clear definition of mountain fever and a consequent misconception of what is meant when the term is used by persons holding different views as to its pathology.

The disease which is ushered in by a severe chill, intense headache, and general muscular soreness, with foul, coated tongue, constipation and highly colored urine, and is denominated "mountain fever" by one physician does not satisfy the mental concept of another, who regards the disease as modified typhoid. Heated discussions follow because the disputants are talking about entirely different disease entities. The one has before him the mental picture of a bilious fever, attended by the clogging up of the system, and the sudden formation of toxins which lead to intense systemic disturbances, but which fortunately under proper eliminative treatment are ephemeral in duration. Of many hundreds of cases of this bilious fever treated in Wyoming during the last nineteen years I have rarely known of one to last longer than three or four days.

The other disputant, however, perceives an entirely different thing. He has in mind an insidious, slow on-coming and long-continued fever with its physical prostration and mental perturbation, and has no patience with the man who talks of breaking up the disease in a few days. This being the state of affairs, the first essential is a clear definition of what we mean when we use the term "mountain fever." I believe that in the interests of truth and scientific medicine the term should be dropped and consigned to the oblivion which has overtaken the popular term "typhomalarial fever" of two decades ago; but since it is with us let us see what can be done with it. As used in this paper the term "mountain fever" will mean typhoid fever as modified by the local conditions and climatic influences of the Rocky Mountain region, and I shall briefly outline my reasons for so defining it.

Post-mortem examinations made by a number of competent observers have shown that the lesions are identical with those found in typhoid fever in our Eastern States. This was very clearly demonstrated nearly twenty years ago by a surgeon in the United States Army who, in seven or eight autopsies in cases of this kind, found the characteristic enlargement and ulceration of Peyer's patches and other lesions typical of typhoid fever in every one of them. These earlier observations have been corroborated by more recent ones. Dr. Charles E. Woodruff, U. S. A. (*Jour. Amer. Med. Ass'n.*, April 2, 1898), writes as follows: "Whenever a case went to the post-mortem table the lesions of typhoid fever were invariably found, so that a few physicians dropped the term (mountain fever) at once." I desire to call your earnest attention to Dr. Woodruff's paper, to which reference has been made, as it is based on thirty-five cases treated at the United States Hospital at Fort Custer, Montana. The cases are fully recorded and carefully analyzed, and are particularly valuable because in nearly all (30) repeated blood-tests according to Widal's method were made. It is a curious, suggestive and instructive fact that while in many of the cases the earlier examinations gave negative results, the later ones, and some well on during convalescence, gave positive reactions; all the patients examined, with one exception, gave a positive Widal reaction at some time during the course of the disease. (In three recent cases of my own the positive Widal reaction was obtained.) We thus see that post-mortem examinations and bacteriologic investigations unite in declaring "mountain fever" to be an atypical form of typhoid fever.

Let us now briefly glance at the symptoms which characterize the disease. In nearly all cases it is ushered in by malaise, headache, a quite decided chill, or chilly sensations, and fugitive pains in the muscles, especially in the back. The headache ordinarily subsides in a few days, especially when

[1] Read at the third annual meeting of the Wyoming State Medical Society, held at Laramie, Wyo., October 10 and 11, 1899.

the patient is put to bed early and kept perfectly quiet. The tongue is always more or less coated. In mild cases the coating may be merely a thin white fur, but in severe ones it is yellowish-brown, and may cover the whole dorsum of the organ. The breath is foul, of a sweetish odor, and there is often a bad taste in the mouth; this is sometimes attended by anorexia and loss of appetite. One peculiar characteristic of the disease is the prevalence of constipation, which is present in the great majority of cases. Out of the twenty-five or thirty cases I have seen well-marked diarrhea was present in only a couple of instances. The lenticular rose-colored spots are quite frequently present, and right iliac gurgling is found in the early stage in most cases.

The temperature presents a regular typhoid curve in many instances, but in others it pursues an atypical course. These irregularities are found particularly during the convalescent stage. After having been normal in the evening for a number of days the temperature without any ascertainable cause, will often go up to 101° or 103° F., and after remaining there for a few days will return again to the normal. The temperature in my own cases ranged from 101° to 105° F.

The liver and spleen are enlarged in a considerable proportion of cases, and abdominal distention and tympanites are present with varying frequency. Sometimes a series of cases will be found in which these symptoms are present in the majority, while in another series their presence is the exception. Mental hebetude, maniacal, or low muttering delirium and extreme physical prostration are not frequently found, but this I believe is due rather to more intelligent and rational methods of treatment than to any change in the severity of the disease. The pulse varies generally between 90 and 120 per minute, and rarely in my experience exceeds the latter rate. It sometimes becomes dicrotic or intermittent. At the present time I have a seriously ill patient under treatment in whom the pulse intermitted every fifth or sixth beat, but under the action of strychnin and other heart tonics the intermittency appeared at longer intervals, once in twenty beats, and finally disappeared. The urine is high-colored, and often is passed at infrequent intervals, in some cases only once in twenty-four hours. Epistaxis is only rarely present during the prodromal period, but is a more frequent symptom after the establishment of the disease.

In speaking of complications in his thirty-five cases Woodruff says: "Bronchitis was rare, only three or four cases. There was no pneumonia; intestinal hemorrhage was several times suspected from sudden falls of temperature, but in no case did blood appear in the stools." In my own cases I have never met one of frank pneumonia, but in one long-continued case, in a child eight years of age, there was hypostatic pneumonia. In this same case, owing to the intense systemic infection, pyemia supervened and both parotid glands suppurated, and had to be lanced, discharging a large amount of pus. This case is corroborative proof of the typhoid nature of the disease, because a parotid suppuration is a rare complication of typhoid fever. Austin Flint, Sr., reported that he saw only six cases of this complication in typhoid fever in all his enormous clinical experience.

Through the courtesy of Dr. Solier I saw one case of severe intestinal hemorrhage, but have never had that complication in my own practice. I did see one case of intestinal paresis or paralysis, due to improper diet, which from the fatal termination is of sufficient interest to report. Three or four years ago I treated Mrs. R., a large, fleshy woman, mother of several children, for a severe attack of typhoid fever. The temperature ran high, 104° to 105° F. for nearly two weeks. Pulse was weak, and heart-failure had to be constantly guarded against. The case pursued a favorable course, however, and the fever gradually subsided until the temperature reached normal. With careful instructions as to diet and exercise I dismissed the patient, but requested the husband to notify me at once if any unfavorable symptoms made their appearance. Three or four days later I was hastily summoned to see the woman and found her gasping for breath, her abdomen distended, as tight as a drum, and her pulse very rapid and almost imperceptible. On asking the cause of this state of affairs I was informed that she had been doing nicely until that day, when a kind (?) neighbor had brought in a large plateful of apple cobbler, and the patient had eaten the whole of it at one sitting. I introduced a large rectal tube, piped off some of the gas, gave her heart tonics and stimulants, as well as carminatives and digestants, and in a few hours she was in a fairly comfortable condition. At this juncture, however, the husband was persuaded by over-solicitous and philanthropic neighbors to change doctors. The patient was placed under the charge of another physician, and after suffering intensely for about two weeks passed into the hands of the undertaker.

The fatal termination of this case impressed upon me strongly the importance of careful regulation of the diet in all these fever cases, even for a considerable time after the subsidence of the fever and the establishment of convalescence. This precaution is particularly important in view of the fact that recurrences of the fever or relapses are very frequent,

even a week or more after the temperature has become normal. Of course, intestinal perforation is a contingency that must always be present in the mind of the physician, but fortunately it rarely occurs.

Since the disease is caused by the Koch-Eberth bacillus, and is communicated principally by means of drinking-water, milk, and by flies (*Jour. Amer. Med. Assn.*, September 2, 1899) which, by coming in contact with the dejecta convey infective material from the sick to the well, every possible precaution should be taken to sterilize the dejecta, both feces and urine (it is now known that the urine of typhoid patients may contain the germs for many months, *Jour. Amer. Med. Ass'n.*, September 9, 1899) and dispose of it so as to protect the community against the ravages of the disease.

While to the physician a careful study of the symptoms and pathological lesions in order to arrive at a correct diagnosis is a matter of great importance, rigid measures of prophylaxis to prevent the spread of the disease is of the greatest moment to the community. To the person down with the fever the question which transcends all others is, What treatment will give the greatest chance for recovery and afford most relief to my sufferings? As practical physicians whose principal function it is to mitigate suffering and save life, let us see what treatment is the best to pursue in combating this disease. We are here confronted by a malady whose death-dealing toxins penetrate to the very citadel of life, and the most active resistance on the part of the protecting forces of the organism is necessary in order to overcome the disease.

Fierce wars have been waged by the advocates of different methods of treatment, from the copious venesection of our forefathers to latter-day nihilism, and the smoke of battle still envelops the contending partisans. This state of affairs makes it necessary that the physician should possess a clear conception of the disease, that he have good common sense, that he have faith in the efficacy of properly applied medicinal agents, and that his mental vision be not befogged by any restricted methods or fad. There are two guiding principles which I believe should never be lost sight of in the treatment of any disease, and which apply with peculiar force to the disease under discussion: First, inhibit or destroy the pathogenic micro-organisms, and neutralize or eliminate their poisonous toxins; second, strengthen the phagocytes and cells of the body and conserve the bodily forces in their battle against the morbific agents. With these broad general principles clearly in mind let us see what can be done when confronted by a case in actual practice. First, put the patient to bed in a cool, well-ventilated room, and surround him by the best possible sanitary and hygienic conditions. In carrying out our first principle in our battle against the micro-organisms and their toxins I believe an eliminative and antiseptic treatment occupies a very prominent place. During the first few days I give, hourly, tablets containing ½ a grain each of calomel and sodium bicarbonate until free catharsis is produced. The calomel acts on the liver, producing a free flow of bile, and has a cathartic action, and, as was shown by Dürhssen several years ago, also has a decided diuretic effect. By these different actions a large amount of toxic material is carried out of the system. Furthermore, calomel is a potent antiseptic and exerts an inhibitive effect on the bacilli causing the disease. Many writers assert that the good effects claimed for the antiseptic treatment is a figment of the imagination, and that sufficient antiseptic material to kill the bacilli would be fatal to the patient. I suppose some of this audience have at times observed the condition of sluggish streams near our Western towns; they teem with dead dogs, cats, and filth of every description. They are an insult to our ideals of the eternal fitness of things, and no one would invoke their aid in allaying an irritable stomach, or in restoring a failing appetite; but let a sudden freshet come on, and behold the change! The decomposing animal matter and foul stenches almost instantly disappear and from being nauseous and disgusting the place becomes pleasant and salubrious.

It has required no powerful antiseptic nor chemical action to effect this change, but plain water and a physical washing-out process has accomplished it. The alimentary canal during the early stages of typhoid fever can be appropriately compared to a foul stream and the calomel has much the same effect on the system as the freshet has on the sluggish stream; it washes out the feces, decomposing material, bacilli, etc., and cleans the alimentary canal from one end to the other. This removes the bacilli and accumulated toxins and places the bowels if not in a surgically clean, at least in a vastly improved condition, and removes an incubus from the whole system. The toxin-poisoned cells arouse from their lethargic state, the headache disappears, and the countenance assumes a brighter and more cheerful aspect. But the medical nihilist confronts us with "My dear sir, don't you know that the bacilli have already penetrated deep into the bowels, and are beyond your antiseptics and flushing; and don't you know that typhoid fever pursues an unalterable course no more to be changed than the laws of the Medes and Persians, and any attempt to

abort or cut short the disease is a sacrilegious flying into the face of Nature?" and much more of a similar kind of logic. Yes, my dear sir, we know all about that; but with all due respect for the great pathologists of the country, with whom the post-mortem is often the most important part of a case, and the medical nihilists who can see no virtue in therapeutic agents, we must differ. With hundreds of honest, painstaking and conscientious physicians all over our country we believe the course of the disease can be shortened and the severity of its symptoms mitigated. If it is good treatment and hastens the healing process to drain and cleanse a wound on the surface of the body as thoroughly as possible, why is it not good treatment to resort to similar measures in treating the bowel?

After the first few days of the cathartic treatment above described, the effect should be continued by giving enough antiseptic and eliminative medicines to produce several free passages each day. When the stomach will tolerate it I have found that the Woodbridge tablet No. 1, one or two every hour, acts very well. Salol and arsenite of copper can be used to good advantage in some cases, and in several instances recently I have obtained very good results from a tablet composed of equal parts of sulphocarbolate of zinc, lime and soda, 5 grains in each tablet, given four or five times a day when the bowels are acting freely. The indications must be carefully studied and the particular antiseptics selected to meet these indications in each case.

The cold bath is one of the approved methods of treatment, and has many earnest advocates, so earnest, I have often thought, that they fail to see the good in other methods of treatment. There is no question as to the good effects of the cold bath, and I have used it with excellent results in a number of cases. It lowers the temperature from one to three or four degrees, tones up the nervous system, strengthens the heart, and largely increases the amount of urine and toxic materials eliminated by the kidneys, but while these beneficent results follow the use of the cold bath, it is claimed on the other hand that the application of cold to the surface of the body considerably increases the tendency to intestinal hemorrhage, as well as the fatality following that accident.

Dr. Roland G. Curtin of Philadelphia (*Jour. Amer. Med. Assn.*, September 25, 1897), after a careful analysis of sixty hemorrhagic cases, as furnished by the hospital records, writes as follows: "When you take into consideration that the application of cold drives the blood from the surface of the body it must necessarily be followed by an increased amount in the interior, causing a congested condition of the internal organs, and if there happens to be a blood vessel weakened or opened by the operative process it may give way or a clot be dislodged, and a hemorrhage follow. The necessary disturbance in giving a cold bath or the reaction following it may have a tendency to produce the same result. These statistics would seem to indicate that it would be well to avoid cold applications to the skin when there is a tendency to hemorrhage, or when it has already occurred. I would also suggest that during the third week, when the sloughing process is most active, the cold bath or pack, if used at all, be used with great care, avoiding sudden and marked impressions on the external circulation; we may in this way avoid making the case a hemorrhagic one."

Then, too, the almost insuperable difficulty of giving these cold baths in private practice is a serious objection to the treatment. Many ingenious devices have been suggested for overcoming the difficulty, but when tried in the crucible of experience are found to be unsatisfactory. Fortunately, however, I believe we have within our reach a method which is always available and easy of application, and while possessing the advantages of the cold bath is free from its inconveniences and dangers. I refer to the intrarectal injection of cold normal salt solution. I have seen the use of cold water per rectum advocated, but so far as I know the use of the normal salt solution for this purpose is a thought original with myself. By these injections, using either a bed pan or a Kelly-pad to protect the bed, one avoids disturbing the patient or causing movement on his part. By means of a fountain-syringe hung up at the head of the bed these injections can be given without fuss, muss, or trouble of any kind. The first one will probably come away, bringing with it some feces, thereby cleansing the bowel; subsequent ones may come away after a time, but if they do they abstract a large amount of heat; often, however, they are retained, and the water passes out through the skin and kidneys, principally the latter, for Dr. W. H. Thompson has ascertained that normal salt solution causes a marked increase in the amount of urine, and of the urea contained in it (*Journal of the American Medical Association*, August 26, 1899). These cold normal salt solutions (and I would advise very cold, even ice-water, when the fever is high) reduce the temperature, calm nervous irritability, and tone up the nervous system, strengthen the heart, eliminate toxins from the system, and prevent, instead of cause, internal congestion. I have used them in a number of cases with very beneficial results, and in a recent very severe case, with tympanitic disten-

tion and tenderness of the abdomen, headache, temperature 104° F., dicrotic pulse, sordes on the teeth—in short, a case of profound toxemia, the relief was almost instantaneous. The patient's temperature declined, the pulse became more regular and stronger, and the countenance assumed a look of peace and contentment instead of its former pained expression.

As a heart-tonic I rely principally on strychnin, but occasionally find Da Costa's heart tonic tablets a valuable adjunct. Each contains nitroglycerin, $\frac{1}{100}$ of a grain; tincture of digitalis, 2 minims; tincture of strophanthus, 2 minims, and tincture of belladonna, $\frac{1}{4}$ of a minim.

I restrict the diet to milk, buttermilk, or other liquid nourishment. By this treatment the disease not only runs a shorter course, but the symptoms are greatly mitigated in severity, delirium is scarcely ever present, and physical prostration is much less marked than under the old methods of treatment, which furnished a continual banquet for the bacilli and permitted constantly increasing amounts of toxin to circulate through the system, poisoning the blood, poisoning the brain, poisoning every cell and tissue of the body, while at the same time the patient was drenched with enormous doses of brandy or whisky, an ablation, doubtless, to Charon, who ferried them over the Styx.

YELLOW FEVER AS A SCOURGE IN THE UNITED STATES.

BY G. HEUSTIS FONDÉ, M.D.,
OF MOBILE, ALA.[1]

A REVIEW of the history of the yellow-fever epidemic in the United States is encouraging. To recall the epidemics which swept through the cities of New Orleans, Mobile, Memphis and Norfolk, which were virulent and fatal, it is necessary to go back some twenty years or more. The mortality of the disease at that time was appalling and sufficient to leave the impress which the name "yellow fever" brings only to those familiar with its past history. But at the present day we find that the disease is becoming milder and milder, so mild, in fact, that some of the older physicians are loath to acknowledge that it is the same disease with which they were familiar. Yet, that it is the same disease in every respect, except in degree, is beyond question, for while the large majority of cases are almost trivial attacks so far as life is concerned, in a greater number of cases a few will be found which are of a most malignant type. That the lessened mortality is due in great part to a more thorough understanding of the disease and rationale in treatment cannot be doubted by those familiar with it, but that yellow fever has become attenuated and generally milder is also beyond dispute. The explanation of this lessened virulence may be found, perhaps, in the enlightenment of the physicians and public as to the conditions which favor the propagation of the germs in increased virulence and concentration. This particularly applies to room and house infection. That the disease is disseminated and spreads almost entirely through the medium of house infection is evidenced by watching the first cases of an epidemic and tracing the visits of the patients to sick friends at night or for several hours in the day in ill-ventilated rooms or rooms suitable to retain the infection until it reaches sufficient concentration to become a danger to the non-immune. That it is seldom if ever contracted by direct contagion is the opinion of those most familiar with the disease.

In illustration of this theory there are institutional statistics showing that yellow-fever patients have been treated in wards filled with non-immune patients and attended by nurses and physicians not immune without the spread of the disease. In one instance of this kind the beds intervening between the yellow-fever patients were occupied by surgical non-immune and confinement patients, and yet the disease was not contracted by any one in the ward or building. This is accounted for by the theory that the disease is not *directly* contagious; that the yellow-fever patient first infects his personal clothing and bed or room, the infection then undergoing some change or increase and becoming sufficiently virulent or concentrated to endanger those susceptible to the disease. It has been proved by keeping the bed-clothing, linen and wards fresh and clean, and by disinfection of the surroundings that the disease can be checked not only in a city but within the confines of the same walls. Supposing that thorough disinfection was not attained in a ward, but that the degree of concentration of the infection and the media for growth of the germ or development of the infection were unfavorable, then one contracting the disease from such a source would probably suffer from a milder type than if the infection had been from a ranker crop of germs, though of course this would vary also according to individual resistance or susceptibility. Apply this to an epidemic and one can account to some extent for the more attenuated form of the disease which has characterized the outbreaks of the past fifteen or twenty years.

Again, the lessened mortality of to-day may with a strong probability of correctness be accounted for by the failure to diagnose and report the very mild

[1] In charge Yellow-Fever Camp for city of Mobile in 1897; Acting-Assistant Surgeon, U. S. A., on Yellow-Fever service, 1898; Acting-Assistant, Marine Hospital Service, on Yellow-Fever service in Agric. & Mech. College of Mississippi, 1898; on Yellow-Fever service, National Soldiers' Home, Va., 1899.

cases in the years past. At any rate, it can be said positively to-day that the recent epidemics would show even a much smaller mortality-rate if every mild case of yellow fever were reported. It would seem incredible, then, that the name "yellow fever," to-day could create a greater panic than numerous epidemic diseases of the North, as well as the South, which are much more fatal, and more tedious and treacherous than yellow fever.

It might be asked if it would not be in line with this argument to favor abandonment of quarantine and obstruction to traffic and allow the disease to immunize the South for a generation and a half to come. Perhaps such a view will not prove a bad one, but we must not jump to the other extreme now. We can resist the progress of the disease if it is not too mild to bear all the ear-marks and consequently does not slip through the lines without warning because of its lightness. While reason and recent experience should make us feel safe from future death-dealing epidemics of yellow fever, conservative judgment would not permit letting the bars down and trusting the disease too early in the yellow-fever season, because it is known of all epidemic diseases as well as of yellow fever that as the epidemic grows older the disease grows more virulent in form. Late in the yellow-fever season the appearance of a mild form of the disease should cause no alarm, even if quarantine restrictions—and by this the retarding if not absolute checking of the spread of the disease—be abandoned, though there would be greater security and little inconvenience to the public to continue house quarantine and local measures.

That thorough disinfection, isolation and quarantine measures not only can check an epidemic but can and have stamped it out in this country is demonstrated by its accomplishment recently at the National Soldiers' Home, in Virginia (with some thirty-five hundred inmates), and in the town of Phoebus. Other instances might be cited. On the other hand it seems only reasonable to conclude that where conditions of climate, soil, and unsanitary surroundings prevail, as in Cuba, and where the infection would not only be propagated in houses and people but is widespread in the soil of the locality, it would then only be possible to check the spread of the disease by confining it to one region, and its stamping out or extermination would be practically beyond artificial means unless in a very limited area. From this example, an illustrative proposition, the Gulf and South Atlantic States, which are not the natural habitat of the disease, can and will unquestionably be able to stamp out infection if discovered early and check or control all outbreaks of yellow fever sufficiently to make it no longer the dreaded scourge of the South, though it seems now not sufficiently fatal or severe to be dreaded even if it were impossible to control it.

Thirty years ago the announcement of one case in a city like New Orleans would have been followed by such rapid geometrical progression of foci from the primary one that it was then proper perhaps to consider the whole city as infected, but with the present methods of guarding, isolating and disinfecting such should not be the case. The discovered infected foci are of very little danger to the city of New Orleans, much less to other cities.

In regard to keeping the disease beyond the border of the United States, we have learned valuable lessons from the recent outbreaks which should not fail to be of future benefit in solving the question with even greater ease than that assumed in the foregoing discussion. The Southern ports are supposed to have uniform quarantine regulations. The lack of uniformity and thoroughness of detail in the work are patent to the observer in quarantine matters and no doubt will soon be corrected. However, of great importance to the South, both from a sanitary and a trade point of view, is the outbreak in Virginia this season, the case in the city of Washington last season, and still another the season before in New York City, in the person of Colonel Waring.

The infection has gained entrance three consecutive years through the New York quarantine station, in two instances the disease being well developed at the time of inspection, or supposed inspection, by the New York quarantine officer, and in the last instance in some old quilts and plunder from Santiago which escaped fumigation. The bearing of this from a sanitary point of view is evident: persons and baggage entering New York, Baltimore and other ports from the tropics can reach the South more promptly than by entrance through Southern ports, on account of quarantine detention. This being a fact, the regulations should be, if not the same for the North Atlantic ports, at least proportionate to the liability of infection. The bearing of this from a trade point of view is also evident: these ports are competitors of the Southern ports for the tropical trade and should not be allowed an advantage in quarantine restrictions which renders the South less secure than those which are self-imposed and necessary for the protection of her ports and adjacent country.

CONGENITAL TUMORS OF THE FINGERS.

By CHARLES E. FAIRMAN, M.D.,
of Lyndonville, N. Y.

My studies of this subject originated from the occurrence in my practice of two congenital neoplasms in new-born infants, the nature of which, owing to

their comparative rarity, was at first somewhat uncertain. Briefly stated, the cases were as follows:

CASE I.—September 23, 1895, Mrs. W. P., of Oak Orchard, Orleans County, N. Y., was delivered of a child which had a tumor nearly half an inch in length and one-third of an inch in diameter attached by a narrow pedicle to the outer surface of one of its little fingers. On the morning of September 24th I removed the growth by severing the pedicle with scissors. Rather free bleeding followed, which was controlled by applications of bismuth subnitrate. The healing was rapid. The growth resembled a supernumerary digit which, according to Reynolds,[1] may be attached by skin only.

After hardening in alcohol, sections stained with borax-carmine revealed normal epidermal tissue on the exterior, while internally there was a central space filled with granular semi-sebaceous material. The central cavity was lined with epidermal tissue in no way to be distinguished from that on the exterior surface of the tumor. Numerous hairs were included in the substance proper of the growth. Nothing was seen which resembled a cross section of a supernumerary digit or a fetal finger. (Clarkson.[2] Fig. 137.) The growth was a dermoid tumor.

CASE II.—September 12, 1897, to Mrs. I. V., of County Line, Niagara County, N. Y., was born a son with a similar growth upon the thumb of the right hand. This was removed September 13th without any difficulty.

An examination of the thumb eighteen months after the operation showed that it was atrophied and considerably smaller than the left one. The distal phalanx was somewhat abducted. The mother remarked that "it looked more like a finger than a thumb." All the articulations of the thumb were abnormally relaxed and movable, giving the appearance of partial luxation, and there was a band of tissue along the outside of the thumb, partly cicatricial, which doubtless had some part in the abduction of the distal phalanx.

Féré[11] has recently described some cases of luxation of the thumb in children affected with unilateral or bilateral paralysis, and points out that besides the luxation there were present other evidences of defective development, such as small size of the thumbs, etc. In my cases I conclude with Féré that these phenomena (dermoid tumor, joint laxity, smallness of the thumb and abduction) are the results of the same development defect.

If a case similar to Case II. should ever present itself I should urge the use of the Röntgen-rays. This would show if, in addition to the tumor, there was defective development of the osseous structures of the finger, and allow proper treatment to be instituted Joachimstal[3] was the first to call attention to the great value of the Röntgen-rays in such congenital anomalies.

In another communication, "Ueber Brachydaktylie und Hyperphalangie," Joachimstal[4] emphasizes the value of the X-rays in the examination of fingers abnormally short or long. After recapitulation of three cases of Leboucq, he describes the case of a twenty-seven-year-old woman with index- and middle-fingers of one hand very much shortened, and a long index-finger on the other hand, and in the twenty-two-year-old sister of the preceding patient a similar defect. A son and a niece of the first woman had the same peculiarities. Subjected to the Röntgen-rays these cases of short fingers proved to be due, not to a diminution in the number of the phalanges, but to a reduction in the normal length of the individual members. (The occurrence of these cases of Joachimstal in one family brings to mind the observations of Dr. D. Young[5] on "Hereditary Digital Abnormality," in which he describes a family which have what they call "straight thumbs," *i. e.*, broad ankylosed terminal phalanges, transmitted from the paternal side.) Hawkins-Ambler[30] investigated a case of unequal growth of the fingers with the Röntgen-rays, and agrees with the view of Crawford that it was caused by incomplete division of the cartilage and deficient nutrient supply in consequence. Gerrish[6] says that the cause of makrodactylia, in which from excessive nutrition the digits are enormously enlarged, is unknown. He gives an illustration of the disease occurring in two fingers of one hand and three of the other, to which the reader is referred.

Dermoids of the limbs and fingers are classed by Sutton as implantation dermoids. Dr. Roswell Park[7] tells us that "they are rare and usually associated with antecedent injury, by which epiblastic structures are driven in and implanted in such a way that as they develop they give rise to these peculiar tumors." Ziegler[8] considers them to be due to aberrant germinal cutaneous cells from the epiblast which have wandered to an abnormal site. H. Ribbert[10] has investigated the experimental production of epithelial and dermoid cysts, and says that they can only be produced experimentally when pieces of epithelium are implanted along with connective tissue to which they are physiologically attached. This connective tissue has an office to perform in affording nourishment to the implanted epithelial cells. Under these precautions Ribbert used indifferently in his researches epithelium from the epidermis, from the mucous membrane of the mouth, and from the conjunctiva. Small pieces were implanted in the lymph glands, the posterior chamber of the eye, under the skin, and in the abdominal cavity. In consequence of secondary changes the relationship of the implanted epithelium to that of the experimentally produced cyst

cannot always with certainty be traced. Ribbert considers that epithelial and dermoid cysts originate in the human being oftener than they are observed, many of them failing to mature and finally disappearing, a frequent occurrence, as might readily be imagined in the experimental production of these tumors.

In a case of supposed congenital tumor of the fingers the following conditions might come up for consideration: Supernumerary fingers; makrodactylia with brachydactylia; congenital hypertrophy associated with lipoma (this sometimes occurs in the foot, Blackader[13]); exostosis (Simonart[14]); dactylitis syphilitica; tuberculous disease of the fingers (Bennett[12]); lipoma (Ranke[15]); sarcoma; new growths of traumatic origin; corpora oryzoidea.

As regards congenital deformities and abnormalities nothing farther need be said, for the reasons that I have already briefly considered them, and the diagnostic features are treated in various text-books.

Tuberculous disease of the fingers, according to Kauders,[16] has a peculiar appearance, the affected fingers being enlarged in a spindle-shaped manner, the bones appearing puffed up (*aufgeblaht*). Sometimes the swelling is elastic, but may be hard, the overlying skin edematous, at times reddened and hot. The disease mostly attacks scrofulous children, and family history is an important element in diagnosis. According to Sturgis,[18] the first sign of syphilitic dactylitis is an enlargement of the shaft of the bone, which may be at times painful, the swelling hard at first being followed by softening and necrosis, shortening, and a useless finger. Congenital enchondromata or exostoses may be distinguished from syphilitic dactylitis by "more localized swellings, limited to a portion of the circumference of the bone" (Van Harlingen[17]). The reader is referred to works on hereditary syphilis and syphilis of the osseous system. Clubbed fingers occurring in congenital heart disease or as a result of empyema or phthisis, and arthritic enlargements of a gouty or rheumatic character, ought not to present any difficulty in diagnosis.

Microscopic examination may be necessary to decide the question, as sebaceous cysts, often have been taken for dermoids, or *vice versa*.

Sarcoma in its various forms attacks the fingers. For instance, Wheeler[32] describes a case of melanotic sarcoma of the right index-finger; Turner,[33] a case of osteosarcoma of three fingers; La Grange,[35] a case of simple sarcoma of the little finger; while A. Cartaz[34] has put on record an affection of the first phalanx which he calls "sarcome periostique." Sarcomatous tumors of the fingers vary in size, some reaching such proportions as to be noteworthy (O'Grady[31]). Any of the fingers may be the seat of the neoplasm.

Digital tumors may be the result of traumatism. Thus, Hamilton[19] narrates a case of traumatic enchondroma of the finger, and Spasokukotski[20] has observed a traumatic epithelial cyst of the fingers. A history of an injury would facilitate the diagnosis and clear up any doubt. The observer having excluded congenital hypertrophies and malformations, deformities due to tuberculosis, syphilis, heart disease and gout, as well as traumatism, and coming to the conclusion that the case is one of congenital tumor would be obliged to discriminate between the following (Monory[21]): Dermoid, epithelial sebaceous tumors or cysts; enchondromata (of the thumb; see Isenschmid[26]); nevi, cavernous and venous tumors. These are the most frequently recorded congenital digital neoplasms.

That dermoid and allied epithelial cysts are not uncommon may be inferred from a perusal of medical reports, for instance, Rizet[22] has written upon the subject of dermoid cysts of the fingers, Troquart[23] upon an epidermal cyst of the pulp of a finger, and Gibier[24] has also described a cyst of the palmar surface of the second phalanx of the right index-finger. Congenital enchondromata are also frequently mentioned in medical literature. Murchison[25] tells of a cartilaginous tumor, enchondroma of the middle finger, which necessitated amputation, and Labbe[27] narrates a case of congenital venous tumor which was erectile, subcutaneous, and which developed on a finger of a young lad; and Curling[28] has communicated a case of degenerated nevus of the finger. Holmes[29] says that it is often difficult to make a diagnosis of congenital tumor from degenerated nevus without exploratory puncture. He tells us that "a nevus will bleed copiously on puncture, the tissues will feel soft, and the point of the needle will be almost but not quite fixed. In a congenital tumor if solid there will be nothing following the puncture except the minutest quantity of blood; the tissues will feel quite hard, and the point of the needle will be fixed."

When the neoplasm is active or malignant, and actually threatening life, its immediate thorough removal is indicated. Amputation may be necessary in some cases. Cases not active may be left to the judgment of the surgeon, but in those cases in which the tumor forms an unsightly deformity, and is attached by a narrow pedicle, immediate removal is best. But in such apparently simple cases it would be a mistake to comfort the anxious parents with the remark, "after it is snipped off it will never cause any trouble," before an examination of the bones and other tissues of the finger has been made, in or-

der to exclude the possibility of some general developmental defect of which the tumor may be by far the smallest feature. The Röntgen-rays should be used if there is any doubt.

CLINICAL MEMORANDUM.

TUBAL PREGNANCY AND DERMOID CYSTS; REPORT OF A CASE.

BY I. B. PERKINS, M.D.,
OF DENVER, COL.;
CLINICAL PROFESSOR OF GYNECOLOGY IN THE DENVER COLLEGE OF MEDICINE; GYNECOLOGIST TO ARAPAHOE COUNTY HOSPITAL.

EXTRA-UTERINE pregnancy occurs so often that most members of this society have had opportunity to make clinical observations on the subject. Dermoid cyst of the ovary is also not of infrequent occurrence. Statistics compiled by several observers of large experience show that from three to seven and one-half per cent. of all ovarian tumors are dermoid cysts. They usually occur in but one ovary. Dr. Kelly, in twenty-one cases, had but one in which both ovaries were involved. It is generally believed that all dermoids are congenital in origin, although some hold that an occasional one occurring in the ovary may be the result of an interrupted ovarian pregnancy. The case which I wish to report is one of dermoid cyst in both ovaries, and pregnancy in the right Fallopian tube, with almost complete obliteration of the left tube.

Mrs. A., aged forty-one years, American born, intelligent, menstruated first when twenty years of age. The flow was scant at that time, and did not occur again for three years. She was married at the age of twenty-three, and gave birth to a son three years later, which was fifteen years ago. At the birth of her child she had "child-bed" fever, so-called, and was confined to her bed eight weeks, a part of which time she was unconscious. She had high fever, chills, sweats, distention of the abdomen, and much pain, but does not know whether

FIG. 1.

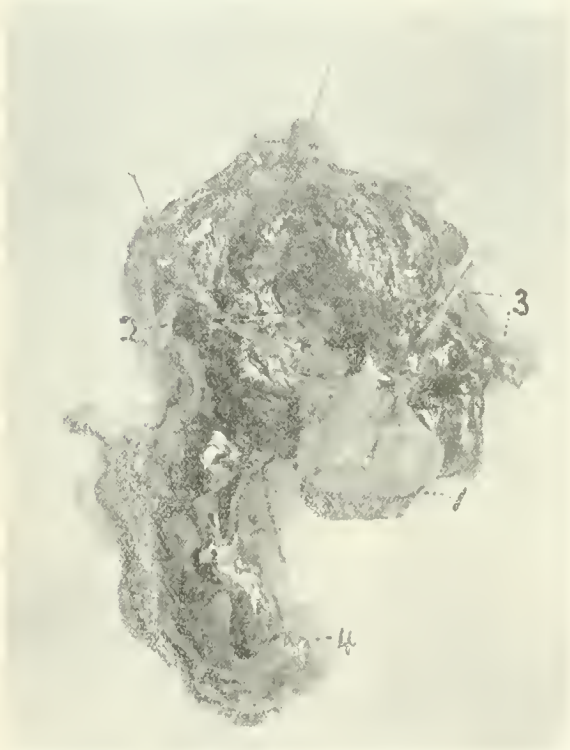
there was an abscess or not—thinks not. Her child was three years old when she next menstruated. The flow was scant and had a bad odor. When most regular she menstruated only three or four times a year, the flow frequently being absent for six or eight months. In the fall of 1898 she menstruated twice in thirty days, the only time this ever occurred. The flow was always scant. From girlhood she had frequently fainted. Seven years ago she had an attack of peritonitis, and was ill five weeks.

I saw her first May 8, 1899, at 1 A. M. She was suffering from severe pain in the right side of the pelvis and abdomen. A tumor, which was quite tender, could be felt on the right side, extending a little above McBurney's point. The pain began four hours before I saw her. It was dull at first, and later became quite severe and

lancinating. From January 30th to April 14th there had been no flow. On the latter date she noticed a scant, stringy discharge, which continued until May 7th, a period of twenty-three days. At the time of my visit shock was intense; her temperature was 95.8° F., her pulse 60, and scarcely perceptible at the wrist. Respiration was sighing, her face and lips were blanched, and she was nauseated, vomiting frequently.

Extra-uterine pregnancy with rupture was diagnosed, and immediate operation advised. She was given a hypodermic injection of ergotin, and one of $\frac{1}{30}$ of a grain of strychnin. Three hours later consent to the operation was obtained. During the interval the strychnin had been repeated three times, and one hypodermic injection of $\frac{1}{100}$ of a grain of atropin had been given. The patient was removed to St. Luke's Hospital, and the operation performed at 5.30 A.M. Her temperature when she was put on the table was 97.5° F., and her pulse 82. Chloroform was administered for a few minutes and ether the remainder of the time. As soon as she was brought into the operating-room injection of normal salt solution under the breasts and into the loose tissues on

FIG. 2.



(1) Fetus in sac. (2) Cavity in tube at point of rupture. (3) Fimbriated end of tube. (4) Uterine end of tube.

the sides was begun, and was continued during the entire operation, a little more than three quarts being used.

A few moments sufficed in which to explore and curette the uterus, which was found to be four inches in length and turned to the left side. It contained considerable shred-like tissue, supposed to be decidual membrane. I removed the rubber gloves, which were used during the curettement, and opened her abdomen, making a median incision about three inches in length. The abdomen was full of dark blood and blood-clots. The incision was enlarged to about six inches, and the abdomen washed out with hot salt solution. The patient was put in the Trendelenburg position. A three-lobe cyst of the left ovary, larger than a teacup, was found resting above the tube and ovary on the right side and firmly

FIG. 3.

(1) Skin covered with scattering hair. (2) Teeth embedded in mass of fat and hair. (3) Bone resembling temporal bone. (4) Cysts filled with clear fluid. (5) Uterine end of tube.

adherent to the intestines. The fimbriated end of the left tube was adherent to the cyst and a small cord (the remains of the tube) extended to its uterine end, which was about two and one-half inches in length and distended with a dark fluid. It ended abruptly, resembling a small sausage. This tumor got its blood-supply through its adhesions to the intestine.

After removing this tumor, the ruptured and still bleeding tube on the right side was readily reached and removed. The sac, containing a three- or four-weeks'-old fetus, was not broken. Before taking a photograph of it in the amniotic fluid, however, the sac was punctured sufficiently to allow the fluid to escape. (Fig. 2.) The right ovary was found to contain a number of small cysts, and was removed. One of these cysts was broken during its removal, and its contents (viscid dark-colored liquid) escaped into the abdominal cavity. The abdomen was thoroughly washed out with normal salt solution, some of which was left in the cavity to be absorbed. Abdominal drainage, with washed-out iodoform gauze, was used, and the wound closed with interrupted silkworm-gut sutures. The operation required forty minutes. The stimulation, in addition to the salt solution given while

the patient was on the table, consisted in the administration of $\frac{1}{15}$ of a grain of strychnin, several doses of sparteïn, and one $\frac{1}{100}$ of a grain of atropin. The patient rallied quickly and made a good recovery.

The drain was removed on the third day and the sinus was found to be infected. This probably resulted from the escape of the cystic fluid into the abdominal cavity, as the contents of dermoids are usually infectious. The sinus has since closed, and the patient is now in good condition.

The three-lobe cyst of the left ovary contained a clear fluid in two lobes, and the third was filled with a thick, fatty substance with hair mixed through it. It also contained a piece of skin covered with hair, a piece of bone

FIG. 4.

(1) Number of small cysts containing fat and hair. (2) Solid body shaped like fetal head. (3) Lock of hair one inch long.

resembling the temporal bone, and a rudimentary portion of the inferior maxillary containing four teeth. The right ovary was divided into six cysts or sections, a majority of which contained a fatty substance, and all of which contained some hair. One of them contained a solid body the size of a small walnut, shaped much like a fetal skull, and covered with fuzzy hair, with one small lock of hair about an inch long in one place. On cutting this mass open it was found to contain lines of gray matter resembling brain tissue.

From the study of this case, I conclude: First, that these dermoids were congenital; second, that the unusual menstrual history was due to the fact that only a very small portion of ovarian tissue was present; third, that the cause of the tubal pregnancy was a contracted tube, due to a salpingitis, and possibly a tubal abscess at the childbirth fifteen years before; fourth, that the destruction of the left tube was due to a twist in the pedicle which shut off the blood-supply from the tumor and resulted in the attack of peritonitis seven years ago, the adhesions from which furnished the tumor with sufficient blood to prevent gangrene.

THERAPEUTIC NOTES.

The Use of Xeroform in the Spanish Army in Cuba.—NOGUERA (*Rev. de Ther. Med.-Chir.*, August 1, 1899), who had occasion to employ xeroform in a number of wounds produced by firearms and swords during the late Cuban war, concluded that it is a powerful antiseptic capable of rendering great service in military surgery. If it does not produce a more active cicatrization than other antiseptic powders, it has the property of absorbing and sterilizing the secretions of the bloody surfaces, thus keeping the wound perfectly dry and protecting it from secondary infection. These properties make it especially valuable for the first dressing of a wound on the field of battle. For the same reason it is useful in hospitals in which attendants are few and not especially well trained. It stimulates the formation of small, firm granulations. Sprinkled on a denuded surface it does not cause pain or irritation. It is not absorbed and therefore does not give rise to intoxication. It is far superior to iodoform and costs less.

The Treatment of Furunculosis of the Ear.—LAMAN, OXEL and MULLER (*Revue de Ther. Med.-Chir.*, August 1, 1899) recommend for use in furunculosis of the external auditory canal an ointment composed as follows:

℞	Zinci oxidi	ʒ j
	Acidi carbolici	gr. x
	Vaselini alb.	ʒ j.

A sound is evenly covered with a layer of cotton upon which the ointment is smeared. This tampon should have a cylindrical shape possessing the same diameter throughout. The greater the swelling of the auditory canal the greater should be the pressure of the tampon. As the swelling disappears the size of the tampon may also be reduced. In order to saturate the tampon thoroughly, it should be twice heated over a lamp and three times immersed in the ointment. The external auditory canal should be douched with a solution of lysol, 20 drops to a glass of water, before the tampon is introduced. The tampon must be large enough to encounter considerable resistance in its introduction. In most cases the first introduction will be extremely painful, but this pain will begin to disappear in four or five minutes. If it fails to do so, the tampon should be withdrawn and a slightly smaller one introduced. The tampon should not protrude beyond the auditory canal. It should be withdrawn after twenty-four hours and the canal syringed. It may be reintroduced if necessary. In ninety per cent. of the cases three applications will be found to be sufficient.

Treatment of Leprosy by Injections of the Oil of Chaulmoogra.—TOUTOULIS-BEY (*Rev. de Therapeut.*, August

15, 1899) treated a patient by injections of the oil of chaulmoogra in order to save the patient the disgust which its odor produces and to avoid the gastric disturbances which follow its administration by mouth. He injected subcutaneously 5 grams (75 minims) of the oil every second or third day. A little pain followed the injection, but there was no inflammatory reaction. The appetite was better than when the oil is taken by mouth, and the nausea and vomiting were altogether avoided. A patient who in 1894 received 128 injections during seven months, recovered the function of his sweat-glands which had been wholly lost. In 1896 106 injections were made. The normal color of the skin reappeared, and the fingers, which up to this time had been flexed, could again be straightened. In 1897 he received 87 injections; in 1898, 50, and in 1899, 33. In all he received about 90 ounces of the oil, each injection representing about 220 drops. The only trace of leprosy which remained was a single nodule in the ulnar region.

Urotropin as a Disinfectant of the Urinary Tract in Cases of Typhoid Fever Attended by Typhoid Bacilli in the Urine.—M. W. Richardson (*Jour. Mass. Assoc. of Boards of Health*, July, 1899) presents the following conclusions: The cases investigated by the writer number one hundred and four, with twenty-three positive results. (1) Typhoid organisms are present in the urine of about 25 per cent. of the cases. (2) The number of the bacilli is often enormous. Indeed, the urine may be distinctly cloudy simply from the organisms present. (3) The bacilli may persist in the urine for weeks, months, or even years after convalescence begins. (4) The virulence of the bacilli obtained from the urine was tested in one instance, and their pathogenic power equalled in every respect that of cultures obtained from the internal organs and the stools. (5) The urine of typhoid patients should, therefore, not only be rigorously disinfected during the disease, but should also be supervised carefully during convalescence.

Studies upon methods for remedying this condition resulted as follows:—(1) Irrigation of the bladder with boric acid (5 per cent.) was of no avail. Corrosive sublimate (1 to 7000) was effective. (2) Salol by the mouth, 10 grains three times daily was effective in a single case. In two cases the bacilli persisted in undiminished numbers. (3) Urotropin was used in nine cases in a dosage of 10 grains three times daily, and with excellent, not to say extraordinary, results. In every instance the organisms were removed. Moreover, this happy result was obtained oftentimes in twenty-four to thirty-six hours; and a urine which had been cloudy with bacteria would in two days become absolutely clear. In two cases, when the urotropin was stopped the bacteria returned to the urine; but a second or third dose of the drug sufficed to remove them entirely.

We have, then, before us a condition, and a remedy for that condition,—a condition the importance of which was recognized nearly ten years ago, but which has never received the attention which it has deserved. The urines in typhoid fever have been utterly neglected, while the stools were rigorously disinfected. The urines are much more to be feared than the stools. To be sure, only 25 per cent. of the cases show infected urines; but the enormous number of the bacteria, and their persistence into convalescence, makes them extremely dangerous, not to the patients themselves,—for they are, of course, immune,—but to those in their environment. We keep our diphtheria patients in quarantine until their throats are free from Klebs-Löffler bacilli. Is it not just as important that typhoid convalescents should be subjected to equally strict supervision? The answer to this question must be in the affirmative. How shall this supervision be carried out? In the first place the urines as well as the feces must be carefully disinfected throughout the disease. Then, as the temperature reaches the normal point, the urine should be examined bacteriologically, to determine the presence or absence of bacilli. If no bacilli are found, then, of course, no active measures are indicated. Before the patient is allowed to go abroad, however,—that is to say, after from two to three weeks,—a second and final examination should be made. If the urine at the beginning of convalescence shows typhoid bacilli, then urotropin should be given in 10-grain doses three times daily for a week. A week after the administration of the urotropin has been stopped, the urine should be examined again. If there are, at that time, no bacilli present, the patient may be released from supervision.

Benzoinol and Resorcin in Diseases of the Throat.—Blair (*Albany Med. Annals*, August, 1899), having tested the various mixtures of resorcin and benzoinol in diseases of the nose and throat, has adopted the following formula as the most satisfactory:

℞	Resorcin	gr. lxxx
	Eucalyptol	gr. x
	Menthol	gr. xx
	Benzoinol	oz. iv.

This mixture possesses the soothing properties of benzoinol which, when applied to the mucous membrane of the nose, will not cause a flow of secretion, and it also has the anesthetic, analgesic, and healing properties of resorcin, menthol, and eucalyptol. It has been used successfully in whooping-cough when sprayed into the nose, larynx, and lungs. In hay-fever and asthma it affords marked relief. In acute laryngitis and aphonia it easily displaces the use of cocain, to which it is far superior, in that it may be used freely without fear of the pernicious after-effects which follow the repeated use of cocain. It is non-poisonous in the dose recommended. The claims made for benzoinol and resorcin compound are thus summed up: It is markedly anesthetic and analgesic. It is antiseptic, astringent, non-poisonous, non-irritating, and healing. It is not suggestive of the drug-shop as iodin, iodoform, and carbolic acid. It has a wider range of effective application than that of any other formula for an atomizer with which the author is familiar.

For Follicular Tonsillitis and Pharyngitis.—

℞	Sodii salicylatis	ʒ ii
	Potassii chloratis	ʒ iv.

M. Sig. Dissolve in one pint of hot water and use as gargle.—*Vansant.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE MEETING OF THE NEW YORK STATE MEDICAL ASSOCIATION.

THE committee of arrangements for the recent meeting of the State Medical Association has abundant reason to congratulate itself and be congratulated on the fruition of its efforts in the great success that crowned this year's session. There has been too much of a spirit of *laissez aller* about the arrangements for the Association's meetings in the past and the enthusiasm evoked by the success of the recent session has been a surprise even to the members themselves. At the meeting last week more than 200 members were registered, while including guests the registration of those in attendance exceeded 300. On Wednesday afternoon, during the interesting discussion on typhoid fever, Hosack Hall at the Academy of Medicine was so crowded that its seating capacity was overtaxed and some of those in attendance were obliged to stand. For the first time the committee was able to secure reduced fares from the railroads on the certificate plan, there being more than 100 members in attendance from outside the city.

The presence at the reception to Drs. Keen, Osler, and Fitz of the most prominent members of the profession in New York City shows how interested all are in this latest phase of the Association's existence.

THE SAVING GRACE OF KNOWLEDGE IN VENEREAL DISEASE.

OUR universities throughout the country have just opened for the year, and hordes of young men, the promise and hope of the land, are already gathered at them. Fortunately or unfortunately, in these later years most of the large universities are situated in the midst of great centers of population. As a consequence, the young man, taken away from conservative home influences at a most susceptible period of life, is set down where the temptations to acts of immorality are only too appealing.

To be forewarned is to be forearmed. One of the points most insisted on, and the subject of a special recommendation at the recent International Conference for the Prevention of Syphilis and Venereal Disease (MEDICAL NEWS, September 30, 1899), was that the youth of all countries should be instructed as to the true significance of venereal disease, and the consequences that immediately and remotely pursue its victims. We have repeatedly taken occasion to call attention to this matter in the columns of the NEWS, and now that distinguished English, German, and French specialists have united in insisting on the necessity for the spread of information on this subject, during the educational period, among the youths of all countries, we deem it appropriate to again direct the attention of the members of university faculties here in America to their serious responsibility in this matter. As Mr. Jonathan Hutchinson said at the Brussels conference, wherever young men congregate there should be furnished to them instruction on the dangers of prostitution and venereal disease.

This is, of course, directly opposed to the Puritanic notions that rule public opinion here in America with regard to this delicate question. We have been accustomed to ignore the existence of the evil, as if, forsooth, our too willing ostrich-like blindness would suppress what we do not see. It is no longer the custom to think that ignorance is innocence. To deliberately suppose that the silence

of education in regard to this subject will foster either innocence or ignorance when so many agencies in our modern life are flaunting its presence would be unmitigated foolishness. The young man is given abundance of information on the subject from any and every source except the proper one.

Of late years the medical profession has learned to regard venereal disease as a much more serious matter than formerly. We now know that in its so-called milder form it is not a simple, readily curable disease. We know that infection and infectiveness may persist for years, sometimes all unknown to the patient. We know that the mutilating operations so often necessary in the case of young wives are frequently due to unconscious venereal infection from the husband. We know that the childlessness of families is not due entirely to barrenness on the part of the wives. We know that in a goodly number of the cases (at least one-fourth) the husbands are responsible. Saddest of all, even when it is a pathological condition in the wife that prevents conception, we know only too often that the condition has been acquired from her unsuspecting husband.

We do not exaggerate; we are stating conditions simply as they appear to medical men at the present time. Much of this comes as a distinct surprise to the lay mind, but it is commonplace in medical circles. We owe it to our young men that they should know something of this. One of the sad things in life, as the physician sees it, is the realization that much of this physical evil is incurred through ignorance. This is all wrong. Let the teaching faculties brush aside this false modesty and incorporate into their bodies a properly qualified medical man who shall speak with authority and with frankness of this great and growing personal and social evil.

We have spoken only of what is called, forsooth, the milder form of venereal disease. Of the dangers of the severe type even medical men seem scarcely as yet to have sounded all the depths. We do know that syphilis has a causative relation to the most serious of mental diseases, general paralysis of the insane, and to the worst and commonest of nervous diseases, tabes, or locomotor ataxia. Whether it may not bear etiologic relations to such severe constitutional diseases as pernicious anemia, diabetes, and other fatal affections remains an open question. We are not syphilophobists, nor do we think a preceding syphilis responsible for every pathologic condition that may develop in after life; we are only feebly expressing the truth as to the new significance syphilitic disease is acquiring in the minds of medical men.

The specialists at the Brussels conference declared that this disease is on the increase all over the world. Each year the duty of disseminating information as to its dangers is becoming more urgent. The duty of university faculties in the matter is to our mind perfectly clear. The young man must not be permitted to gather his information on so important a subject from quacks and charlatans who are interested in exploiting his curiosity and working on his fears. He should be taught by some one he can trust all the modern significance of venereal disease and the dangers to which he exposes himself when he incurs the risk of it. Far from proving an incentive to immorality such information would be a priceless help to the high moral principles that must eventually be his safeguard.

ECHOES AND NEWS.

The Southern Surgical and Gynecological Association.—The Twelfth Annual Meeting of this Association will be held in New Orleans, La., on the 5th, 6th, and 7th of December.

The Charlotte Williams Hospital.—The new public hospital at Richmond, Virginia, is to be named the Charlotte Williams Hospital, in memory of a daughter of Mr. John L. Williams, and that gentleman has contributed $100,000 toward its endowment.

Chicago's Death-Rate.—A total of 495 deaths was recorded in Chicago during the week ending October 23d, being 76 more than the previous week, and 130, or 35 per cent. more then the corresponding week of 1898. This increase is largely due to diphtheria.

Fire in a Hospital.—The City Home and Hospital Building at Findlay, Ohio, was destroyed October 23d by fire, the cause of which was an electric wire. The patients were removed, the last being taken out but a moment before the walls fell. The loss is $60,000.

Diphtheria at Princeton, N. J.—The Public Schools of Princeton were declared closed on October 24th for two weeks on account of the appearance of diphtheria in various parts of the town. The disease is said to be of a mild type and, although it is pretty well diffused through-

out the city, it is thought that the closing of the schools will prevent its further dissemination.

A $1000 Fee.—Coroner's Physician Meshon has sued the city for $1000, the amount of the fee which he declares is due him for conducting an autopsy on the body of H. C. Barnet, who died under circumstances similar to those that obtained in the case of Mrs. Adams, as a result of which Roland B. Molineux is to stand trial on a charge of murder. From the amount of this fee we should judge that the coroner's physician's perquisites greatly overbalance his salary.

Hospital Ship for British Soldiers.—On October 27th the British Government gratefully accepted the offer of the American women in England to equip the steamer "Maine," which has been lent without charge by the Atlantic Transport Company as a hospital for use in South-African waters. This is the same company, an American company by the way, that donated the steamer "Missouri" for use as a hospital ship by the War Department during the Spanish-American War.

Antivivisectionists at the Paris Exposition.—Dr. Luigi Galvani Doane of the Antivivisection Society states that the Society has decided to carry on its missionary work at the Paris Exposition, and that a building will be erected outside the Exposition grounds, in which exhibitions will be given illustrating the methods of the vivisectionists. Literature will be distributed, giving statistics as to the extent of vivisection, and also many alleged arguments from noted surgeons and scientists, explaining the impossibility of applying to human beings the facts demonstrated upon living animals.

Dowie, "the Divine Healer," Mobbed.—John A. Dowie, "the divine healer," was mobbed at Hammond, Indiana, on the night of October 27th, while attempting to deliver an address. He was chased by a yelling crowd, and had he not caught a flying trolley-car just ahead of his pursuers, he would have been seriously injured. Every window in the car in which he took refuge was smashed by stones thrown at him. This demonstration was on account of the death of a little girl afflicted with scarlet fever who was treated by Dowie. The Hammond people believe she might have recovered had she received the treatment of a regular physician.

London Insane Statistics.—There is reason for congratulation that no such condition of affairs exists in American institutions for the insane as is made evident in the report of the London County Council, in which are published statistics of the insane in the public asylums of London. The entire insane population of the public asylums of New York State, for instance, was 21,000 at the close of 1898, while in the institutions of London at the same period there were 14,000. Thus, London, which has a population of not much more than half that of the State of New York, has an insane population of two-thirds as many. Again, in New York the entire net increase in the number of the insane for some time past has not exceeded 650 in any one year. London shows an annual increase never less, in some years greatly exceeding this number.

Asphyxiation by Illuminating-Gas.—A case of accidental death of a prominent man from illuminating-gas has been recently reported at Syracuse, N. Y. The stop-cock of a gas-burner in his sleeping apartments was found partially turned on. A narrow escape from a similar accident recently occurred in a prominent mansion on Madison avenue, New York. It was found that the stop-cock was very loose and easily turned; a hand glass was hanging suspended by a ribbon from the stop-cock. When the person was rescued the stop-cock was found partly turned, and the only satisfactory explanation of the accident is that when the gas was turned off the hand-glass was accidentally set swinging, and the pendulum-motion gradually turned the gas on. *Ergo*, never hang anything on the stop-cock of a gas-fixture.

A Hospital Thief.—A man forty-five years old, in overalls, with tape-line and measures, called October 27th at the Memorial Hospital, at Orange, New Jersey. He told the matron that he had been sent by the local electric company to see what repairs were needed in the electric-lighting system in the hospital, and also to measure the nurses' home for wiring. He was permitted to enter the various rooms. Where there were occupants he made careful measurements and seemed so faithful a worker that he was left alone. When alone he seemed to have neglected electricity for more remunerative work. He took from various rooms money, watches, and personal trinkets. When he had finished he went back to the matron and chatted with her pleasantly a few minutes before bidding her good-bye. He had been gone several hours before the robbery was discovered.

Civilian Surgeons Aid the British Army.—Sir William MacCormac, President of the Royal College of Surgeons and Surgeon-in-Ordinary to the Prince of Wales, has offered, with two other civilian colleagues, to act as consultants at the front in South Africa. Professor MacCormac, whose experience with surgery in the field is unrivaled among Englishmen, has acted in accordance with the view of the Director-General of the Army Medical Department, who considered it would be desirable to have consulting surgeons of large experience with each force. These surgeons would be especially useful in cases for major operation and would relieve the already busy ordinary surgeons of great anxiety and responsibility. During the Franco-Prussian War there were many leading Germany civilian surgeons, and in the Russo-Turkish War many Russian civilian surgeons, and Dr. Nicholas Senn in our recent war gave his services to the Army in a consulting capacity.

Navy Needs More Doctors.—The strongest recommendation in the annual report of Surgeon-General Van Reypen, which was made public on October 23d, is that relating to an increase of the Medical Corps of the Navy. The enlisted force in the Navy has been increased during the past two years, and the Marine Corps has been increased by 3000 men; but there has not been made any provision for a corresponding increase in the Medical Corps, which is charged with the health of these men. Every surgeon who is not sick is on duty and the department has

been unable to supply surgeons for needed recruiting and other duties. It is recommended that five surgeons and twenty assistant surgeons be added to the corps, and that five of the volunteer surgeons who served in the war be transferred to the regular rolls. It is earnestly urged that the naval assistant surgeons be placed on an equality with those of the Army in pay and rank.

The Boer Hospital Service.—It would seem that in the present war the Boer hospital service, concerning which much has been said in depreciation, is in reality very well equipped. The Transvaal has the orthodox Red Cross Society and an efficient St. John's Ambulance Society as auxiliaries to the regular military medical corps. The latter is well equipped, although numerically weak. Several railroad trains have been made ready, fitted with swinging beds and all modern conveniences for alleviating suffering. The women of Pretoria and Johannesburg responded nobly to the invitation to do volunteer duty in nursing "for the sake of their Lord and their country," as the pathetic appeal read. It is said the English nurses have been put out of the hospitals at Johannesburg, the physician in charge insisting that "English women are not fit to nurse the Dutch."

Officers of the New York Medical Association. — The following officers were elected to serve for the ensuing year: President, Dr. E. D. Ferguson of Troy; vice-president for the First district, Dr. Charles H. Glidden of Little Falls; vice-president for the Third district, Dr. J. M. Farrington of Binghampton; vice-president for the Fourth district, Dr. W. H. Thornton of Buffalo; vice-president, for the Fifth district, Dr. J. C. Bierwirth of Brooklyn; treasurer, Dr. E. H. Squibb of Brooklyn; secretary, Dr. M. C. O'Brien of New York City. Council, First district, 1900 term, Dr. Douglas Ayres of Fort Plain; 1901 term, Dr. Charles Munger of Knoxborough; Second district, Dr. E. M. Lyon of Plattsburgh; Third district, Dr. W. L. Ayer of Owego; Fourth district, Dr. M. W. Townsend of Buffalo; Fifth district, Dr. Frederick Holme Wiggin of New York; member of Council at Large, Dr. Joseph D. Bryant of New York City.

Tuberculosis in Old Papers.—The New York State Board of Health has received a communication from the Board of Health of Michigan stating that twenty clerks in that State, who were working over several volumes of records, were taken ill with consumption and had died. The books were examined by a bacteriologist, who found them full of tubercle bacilli. It is thought that they became infected from a clerk who had consumption, and who had the habit of moistening his thumb with saliva when he turned a page. Twenty clerks employed in a German labor bureau were recently taken ill within a short period of time, all of them having worked over records which upon examination by a bacteriologist were found to be infected through and through with tubercle bacilli. Investigation proved that the books had probably been infected by a consumptive clerk who had the habit of moistening his finger in his mouth whenever he turned the pages of a book. Thus all the books had become thoroughly infected.

The Alvarenga Prize. — The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about $180 will be made on July 14, 1900, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in Medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1900. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of the competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1899 has been awarded to Dr. Robert L. Randolph of Baltimore, Md., for his essay, entitled "The Regeneration of the Crystalline Lens; an Experimental Study."

Lockjaw Due to Vaccination.—A despatch from Newburgh, N. Y., announces the death of a young women "from lockjaw brought on by vaccination." The despatch adds that "she was vaccinated in accordance with a compulsory vaccination law." It is quite worthy of belief that lockjaw did follow compulsory vaccination in this case. It is still more worthy of belief, however, that the lockjaw was a post hoc rather than a propter hoc. Lockjaw is a specific disease, the result of a specific infection, and has no more to do with vaccination than it has with a simple scratch upon the skin or an injury to the foot. The germs of tetanus may gain access to the human system through the delicate wound made by the vaccinator just as they may through any other wound. The occurrence, however, is a rare accident, and is entirely irrelevant to the merits or demerits of vaccination as a protection against smallpox. Certain localities seem to harbor the cause of lockjaw, rendering the simplest abrasion of the skin liable to be attended by the most serious possibilities. Newburgh may possibly be such a region, but whether it is or not, the unfortunate event announced in the despatch should not for a moment check the confidence of any sane person in the beneficent effects of vaccination. The more recent report that four children in one family at Highland Falls, near Newburgh, are dangerously ill from probable tetanus following vaccination adds color to the suspicion that that neighborhood is a tetanus-breeding region.

MEDICAL MATTERS IN NEW YORK.

DEATH OF DR. PHILIP SCHEU—DELMONICO FARE AT BELLEVUE — CHAMPAGNE STATISTICS—SMALLPOX CASES—HEBREW CHARITY—NEW DISPENSARY OPPOSED—OCULISTS FAVORED IN DISPENSARIES—GROUNDLESS ARREST OF PHYSICIANS—THE STATE MEDICAL ASSOCIATION.

Dr. Philip Scheu died October 21st of meningitis. He graduated from the College of Physicians and Surgeons and the College of Pharmacy, and was a member

of County Medical Society and the Physicians' Mutual Aid Association. He was forty-one years old.

Maggie Clancy was formerly a laundress in the employ of Charles Delmonico. On October 21st she was caught in an elevator in the Delmonico building, and her right leg was crushed. She was taken to Bellevue, where she is now convalescing. Every day a liveried man drives to Bellevue in a cab and carries to the bedside of Miss Clancy an immense basket containing a Delmonico dinner. She takes all she desires, being served the while by this Delmonico waiter, and then distributes the remainder among her sister patients.

The following statistics should gladden the heart of Dr. Hillis of this city, who has recently given forth a sort of scientific rhapsody in praise of alcohol. In 1898 the amount of champagne exported from France was 19,682,000 liters or bottles, valued at 91,327,552f. (£3,653,100). The export to Great Britain was 10,599,300 liters; Belgium, 2,778,700; Germany, 1,859,200; United States and Canada, 1,419,400; Russia, 498,500; Holland, 468,400; Sweden, 259,200; Denmark, 188,700; Austria and Hungary, 152,300; Switzerland, 141,400; Italy, 129,700; Australia, 125,600; Norway, 108,200; Argentina, 100,300, and India, 100,000.

A two year old child, living in the six-story tenement at 43 Washington street, was found by Dr. Somerset of the Board of Health to have smallpox. The child and its mother were at once sent to the Willard Parker Hospital. Charles H. Brown had been riding on street-cars in Manhattan and Brooklyn for several days before it was discovered that he was suffering from smallpox. He was taken to North Brother's Island in a moribund condition. He had been living in the Glenmore House on the Bowery, after which he went to the Clinton House on Myrtle avenue, Brooklyn. These places have been disinfected, and the sanitary inspectors are watching their lodgers closely.

The United Hebrew Charities celebrated its twenty-fifth anniversary in connection with the annual meeting and election of officers on October 25th. Dr. Lee K. Frankel, manager of the Society, gave in detail the result of his investigation of the alleged pauperizing influences of organized charity. "It is safe to say," he said, "that generally temporary distress is the primal cause of the application, and that as soon as the conditions which produce the distress are removed the application is no longer a burden to the Society."

Dr. Frankel emphasized the alarming increase of tuberculosis among the Hebrews of the congested tenement districts, and declared that owing to inadequate sanitation and the inefficient isolation of the victims of the disease on the part of the health authorities, all attempts of the Society to alleviate suffering caused by consumption had been practically futile. The total receipts of the Society for the fiscal year were $149,748.02, and the disbursements $151,155.48. During the year 4542 new applications for aid were received, and the number of recurrent cases was 18,722. During the twenty-five years of the Society's existence the total receipts had been $2,514,859.53, and the disbursements $2,512,400.64. The number of patients treated was 323,361.

During the past week there was a hearing before Dr. Stephen Smith, of the State Board of Charities, of the application for a charter to be granted to the "Emanuel Hospital and Dispensary," which it was proposed to establish in East Broadway. The application stated that $40,000 was available for the institution, and a further amount of $60,000 had been promised. Members of the Medical League and a number of other physicians were present to oppose the granting of the charter; they insisted that the East Side is abundantly provided with hospitals and dispensaries, and, moreover, nearly the entire population of this district belongs to sick-benefit societies. It was claimed that the Gouverneur Hospital and the Beth Israel Hospital provide ample facilities for the neighborhood. Decision was reserved, although one of the directors of the proposed institution declared after hearing the arguments of the opposition that he would resign.

Louis L. Ferguson, Esq., president of the Optical Society, charges that there is collusion between physicians attached to free clinics and some of the ophthalmic hospitals and certain opticians, whereby the physicians obtain a commission from the sale of glasses to poor patients. Mr. Ferguson declares that dispensary patients having their eyes examined are given prescriptions for glasses written in cipher, and are directed to go to certain opticians to whom alone the cipher is intelligible. "This establishes a practical monoply, and the favored opticians can extort from the patients the largest price possible." Mr. Ferguson cites a number of instances which he considers substantiate his charges.

Dr. Charles H. May, chief of the ophthalmic division of the Vanderbilt Clinic, with whom Mr. Ferguson corresponded on the subject, stated that in his clinic the prescriptions were formerly written in cipher in order to protect the patient against incompetent oculists. These prescriptions were known only to certain opticians of tried reliability. Thus the patients were insured perfectly fitting glasses and indirect recompense was provided to the clinic itself for the expense it is subjected to in supplying free glasses for patients too poor to buy them. The clinic did not receive a commission from its official opticians, but occasionally received lenses and instruments from them. At present the clinic, of which Dr. May is chief, does not make use of a cipher, but telephones the prescriptions to the official oculists.

The following incident illustrates one of the many dangers to which the reputable physician is exposed. Nora Seltz, of 520 Third avenue, died in Bellevue on October 18th from the effects of a criminal operation. Some days before this Miss Mary Reed, of the same address, called to see her, and finding that she was sick, went to Dr. Harry R. Purdy, who visited the patient knowing it to be a charity case, and that he would receive no fee. Dr. Otto Maier also attended on the same understanding. Immediately after her death both these physicians were arrested by Police Captain Delaney, and they both protested that they were in absolute ignorance of the fact that the woman was suffering from a criminal operation,

and stated that they had treated her for rheumatism. Each was put under $1000 bail. At the inquest on October 27th many prominent physicians appeared to testify to the high standing of Drs. Purdy and Maier, but the good sense of Coroner Fitzpatrick rendered such testimony superfluous. The coroner, who was greatly surprised at Captain Delaney's action, dismissed the physicians without requiring explanations of them. They, however, demanded to be put on record, and so each testified concerning his connection with this case. Drs. A. A. Smith and Dr. W. J. Beveridge, house surgeon at Bellevue, testified that there was nothing to show that she was suffering from anything but rheumatism.

Several years ago a young woman in this city died of puerpural sapremia. Shortly before her death, in an ante-mortem statement, she accused a certain physician of having operated upon her. He declared that, although she had called at his office, he had seen her but once, and that, on finding her errand to be to importune him to induce an abortion, he had absolutely refused to treat her, that he had not prescribed for her, and that he had not examined her in any manner whatever. However, he was arrested and imprisoned; he was for a long time under bonds; his name was exploited in the public press in connection with the case, and he had to pay heavily, without hope of remedy, for the services of counsel, not to speak of loss of time, the injury to his practice, and the great mental strain to which he must have been put. Finally, after a number of weeks, his case came up before the grand jury, and that body, in refusing to indict him, placed the guarantee of the law upon the truth of his statement, and established his innocence.

The safest way, though from the experience of Drs. Purdy and Maier we see there is no absolutely safe way, is not to make any examination, digital or otherwise, except in the presence of a colleague, in such cases where one may be called upon to see a patient suffering suspiciously, especially from the more or less disastrous results of a criminal operation. Nor should we induce an abortion, however legitimate the object, without consultation and the assistance of a colleague.

Among those from outside the State in attendance at the meeting of the New York Medical Association last week was Dr. Simmons of Chicago, the editor of the *Journal of the American Medical Association*. He seemed especially pleased that the New York Association was having so successful a meeting, and evidently looks forward to a great increase of its influence and membership as the result of the enthusiasm aroused.

The Health Department submits the following report of contagious diseases for the week ending Saturday, October 28, 1899: Measles, 176 cases, and 8 deaths; diphtheria, 206 cases, and 29 deaths; laryngeal diphtheria (croup), 13 cases, and 8 deaths; scarlet fever, 117 cases, and 4 deaths; smallpox, 4 cases; chickenpox, 18 cases; tuberculosis, 151 cases, and 140 deaths; typhoid fever, 75 cases, and 20 deaths; cerebrospinal meningitis, 6 deaths.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

CHARGE OF ALLEGED SALE OF STATE BOARD EXAMINATION QUESTIONS—DR. WILLIAM M. WELCH ON THE PRESENT MILD TYPE OF SMALLPOX—A FLOATING DISINFECTING PLANT AND HOSPITAL FOR THE STATE QUARANTINE—EXAMINATIONS TO QUALIFY PHARMACISTS—A DINNER TO DR. A. E. TAYLOR—ANOTHER OUTBREAK OF DIPHTHERIA.

PHILADELPHIA, October 30, 1899.

THE charges recently brought by one of the daily newspapers of this city, asserting that wholesale cheating had occurred at the recent State Board examinations, are being searchingly investigated by the members of the Board, and results of an interesting character are anticipated from this probing. It is freely acknowledged that prior to the last examinations held by the Board, certain examination papers were widely circulated, sub rosa, of course, and it is further alleged that these papers were official, and contained the exact questions asked at the examination in question. The sale of such papers was a matter of common and open comment in this city, but whether these papers were actually the result of some untoward leakage from official sources, or whether they were bogus documents, floated by some swindling individual among certain dull cliques in our medical schools—these are questions which the Board is exceedingly desirous of determining. These are malodorous stories to hold the public ear, whether true or false, and it is hoped that the investigation begun by the President of the Board, will effectually disprove their truth.

A description of the present mild type of smallpox prevailing in Philadelphia was the topic presented at the last meeting of the Philadelphia County Medical Society, held October 25th, by Dr. William M. Welch, physician-in-chief of the Municipal Hospital for Contagious Diseases. Dr. Welch attributed the origin of the present form of the disease to importation from the West Indies past year by refugees who, during the Spanish-American War, escaped from Cuba to our Southern States, where infectious foci were established, the disease later spreading to many Northern States. The prevalent type of the disease has been so mild and atypical that it escaped recognition in many instances, being most commonly mistaken for chicken-pox, pustular syphiloderm, and impetigo contagiosa, and this fact alone has much to do with its rapid and extensive spread. In this connection, Dr. Welch took occasion to remark upon the meager knowledge of contagious diseases possessed by the average young medical man, and to remonstrate with city health authorities in general for their attitude in disbarring students from the study of contagious diseases in city hospitals. "It should occasion no surprise that such mistakes in diagnosis occur," continued the speaker, "for young physicians have no instruction regarding the disease. This is not the fault of the student, or of the medical colleges, but of the Board of Health, and if hospitals where such cases are cared for were thrown open to students for instruction many epidemics of this and similar diseases would be prevented." Of 5500 cases of smallpox observed by the speaker,

never before had the type of the disease been so uniformly mild and uncomplicated as during the past year. The vast majority of patients have not remained in bed after the appearance of the eruption, and it has been a novel sight to see unvaccinated patients playing baseball on the grounds of the hospital within eight or ten days after their illness began. The number of smallpox patients at the Municipal Hospital during the past year was 128, all recovering. Of this number 122 were negroes, 92 of them of the male sex, and 110 never having been vaccinated. It is probable that but for the fact that vaccination is in this city widespread and thorough, an epidemic of large dimensions would have resulted from the freedom with which many of these unrecognized cases of smallpox mingled with the other population. The onset of this mild type of the disease differs only in a degree from that of the more severe form. It commences suddenly, often with a chill, or with a slight rigor; the temperature rises to from 101° to 105° F.; there is commonly irritation of the stomach, often intense; lumbar pain is an extremely annoying symptom; and, in adults, there is frequently severe headache. Dizziness and prostration are often absent, and the entire initial stage is so slightly marked that many of the patients are not even confined to bed. In from 48 to 72 hours after the onset of the rigor the eruption appears, the temperature dropping to normal, the other manifestations of the disease rapidly abating, and the disease being practically at an end. The eruption is scanty in most cases; absence of umbilication is often present; and the vesicles change to pustules in four or five days, then almost immediately shrink and begin to dry up. The comparatively slight changes in the skin is a notable point in the disease, the true skin being but little involved, the scabs of small size, and the appearance of pigmented spots taking the place of the usual pit of the severer forms of the disorder. The type of the disease under consideration presents a clinical picture like mild varioloid, although in almost every case there has been no previous vaccination.

The officers of the State Quarantine station at Marcus Hook, on the Delaware, are endeavoring to secure an appropriation for the construction of a floating infection plant and hospital for infectious diseases to supplement the somewhat inadequate facilities of their stations on shore. The proposed vessel will contain a disinfecting-apparatus for the use of steam, similar to that in use on the "Wadsworth," in New York Harbor, and in addition will make use of formaldehyd gas in the disinfection of articles which would be injured if exposed to steam. Adequate bath-and dressing-rooms for patients will be provided, as well as a spacious ward, containing thirty beds, for the reception of patients suffering with contagious diseases.

The members of the Pennsylvania State Pharmaceutical Board have just completed a week's session held for the joint purpose of examining applicants for registration as pharmacists and qualified assistants, and for considering action against violators of the State laws providing for the regulation of the sale of drugs and poisons. In all 236 candidates were examined, only 33 per cent. of whom were successful. Of the total number of applicants 189 applied for registration as pharmacists, and 47 as qualified assistants. At present there are 7 cases awaiting trial in different courts throughout the State for alleged violation of the pharmacy laws, and the Board has also determined in about a dozen other cases that sufficient evidence has now been secured to warrant prosecutions, which will be begun at once.

The friends of Dr. A. E. Taylor, late of the Pepper Laboratory of Clinical Medicine, propose to tender him a complimentary dinner, in honor of his recent election to the chair of pathology in the University of California. The dinner will be given at the University Club on November 7th.

The total number of deaths occurring in this city during the week ending October 28th was 342, or a decrease of 42 from the number reported last week, and of 6 from those of the corresponding week last year. There were 103 new cases of diphtheria, with 19 deaths; 34 new cases of enteric fever, with 4 deaths; and 57 new cases of scarlet fever, with 4 deaths. The increase of new cases of diphtheria is so alarming that the health authorities have ordered an immediate inspection by the city medical inspectors of the public schools, with a view to preventing its spread among school children, by the immediate institution of prophylactic measures wherever needed. It is thought that a few of the schools will have to be temporarily closed for fumigation and disinfection.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

FREE CLINICS—DECISION AGAINST INDEPENDENT MEDICAL COLLEGE—MEDICAL INSPECTORS FOR SCHOOL CHILDREN—CONCEALMENT OF CASES OF SCARLET FEVER AND DIPHTHERIA BY DOWIEITES—VITAL STATISTICS—CONFERENCE OF STATE CHARITIES—PROVISION FOR EPILEPTICS AND INSANE—RESIGNATION OF DR. TICE—OFFICERS OF CHICAGO GYNECOLOGICAL SOCIETY—COMMISSIONER REYNOLDS SUSTAINED—REYNAUD'S DISEASE—PSORIASIS AND DERMATITIS HERPETIFORMIS.

CHICAGO, October 30, 1899.

FREE clinics at the Cook County Hospital is the object of a movement being agitated by the physicians and surgeons in this city. The County Board will be asked at an early meeting to abolish the law that now requires a medical student to pay $5.00 per annum for the privilege of attending surgical and medical clinics. It is said that the County derives a revenue of from two thousand to three thousand dollars for tickets of admission to the clinics. Between seven hundred and eight hundred students attend them. Friends of the officials are given free tickets, and political influences secure the remission of other fees. It is proposed that all be treated alike by giving a ticket to each student regularly matriculated in any recognized college of medicine or surgery. Some limitation may be placed on the time of the student's residence in Chicago, so that Chicago students may be favored in preference to those who live in other cities or outside of Cook County. It is thought to make the

clinics free would be a popular thing for the County Board to do.

The decision of the Circuit Court of Cook County, which excluded the Independent Medical College from the use of its corporate franchises, has just been sustained by the Supreme Court of Illinois. This college, a part of the People's Institute in Chicago, was the successor of the Illinois Health University, the charter of which was revoked by the Supreme Court in May, 1897, for the fraudulent use of diplomas. A few months before the charter of the Illinois Health University was revoked, the Faculty started anew under the name of the Independent Medical College, selling diplomas for a consideration, even though the applicants had not attended an hour at the institution and had no knowledge of medicine. In one case a hostler, living in Pennsylvania, purchased a diploma for $25.00. The Circuit Court of Cook County entered a judgment of ouster against this diploma mill on February 3d last. The college took an appeal from the judgment, which the Supreme Court now affirms.

Dr. W. S. Christopher in order to prevent the spread of contagious diseases has urged the employment of fifty physicians to examine children who have been absent from school four days or more. He presented his plan to the Board of Education and recommended it for adoption. The matter was finally disposed of at a subsequent meeting of the Board and $20,000 appropriated for this year, to be paid out of the school fund. Dr. Christopher believes the inspection will show its value in a decrease in the number of deaths of children from scarlet fever and diphtheria, diseases which always follow the fall opening of the schools. He suggests that the medical inspectors should examine the throats of the children and then make cultures for bacteriologic examination.

Attorney Barnes of the State Board of Health, it is said, will investigate cases where believers in Dowieism have concealed the existence of scarlet fever and diphtheria. As the result of disclosures made by the Health Department, as to the existence of these diseases among children, whose parents believe in Dowieism, the Board will urge the expulsion of Dowie's methods from the State at an early date on the ground that they are a menace to the public health.

An increased death-rate, which it was feared would result from exposure during the Fall Festival, is shown by the monthly report of the Health Department. Every event of public character tending to produce excitement and exposure is clearly marked by the mortuary records of the city from their beginning. A total of 495 deaths were recorded during the week, ending October 23, 1899, being 76 more than the previous week, and 130, or thirty-five cent., more than the corresponding week of 1898. The causes showing the most marked increase are apoplexy, Bright's disease, cancer, consumption, diphtheria, nervous diseases, pneumonia, etc. The weather conditions and the excitement and exposure during the Fall Festival are largely responsible for this increase, but the excessive death-rate of diphtheria, the highest for the year, is probably due to school diffusion of the contagion. Deaths from impure-water diseases continue steadily to decrease, keeping pace with the improving character of the public water-supply since lake dumping has been stopped. Only thirty-two deaths were recorded from these causes last week.

The Conference of State Charities will meet at Bloomington early next month to discuss such questions as the proper provision for epileptics, the care of the feeble-minded, provision for the insane, etc. It is well known that Illinois lacks proper provision for epileptics. The last Legislature appropriated $25 000 to found an institution for their care, and the disposition of this fund and the necessary steps that should be taken for its location will come up at this Conference. Epileptic colonies have been established in New York and Ohio, and the establishment of such a colony in Illinois is greatly desired by the medical profession.

Many questions need thorough discussion from a purely local view. For instance, there are more than 1000 applications on file for admission to the Asylum for the Feeble-Minded Children at Lincoln which cannot be granted because that institution is already overcrowded. There is also insufficient provision for the insane, and Cook County is obliged to maintain at its own expense an institution for the insane of Chicago, which will not accommodate nearly all who ought to be admitted, so that patients are being discharged from it who should be retained.

Dr. Frederick Tice, head physician at the Dunning Infirmary, has tendered his resignation to the County Board, which has been accepted. He contemplates spending two years in study in Europe.

The following officers were elected at the last meeting of the Chicago Gynecological Society: President, Dr. T. J. Watkins; vice-presidents, Drs. Reuben Peterson and L. Frankenthal; treasurer, Dr. A. H. Foster; editor, Dr. Charles S. Bacon; pathologist, Dr. Emil Ries; secretary, Dr. William H. Rumpf.

Mayor Harrison has upheld Commissioner of Health Reynolds in his contention with the drainage trustees and the government contractors, that all dumping within the eight-mile limit was a menace to public life and health. He refused to modify the order issued by Commissioner McGann stopping all dumping within the prescribed limits when the representatives of the Sanitary Board waited upon him with a request that they be permitted to finish their work of excavating this fall and dump the refuse off Thirty-fifth street, as was formerly done. Mayor Harrison thought the sanitary district could better afford to expend $15,000 or $20,000 to utilize the basin off Lake Park Front than the city government could to allow the dumping to go on within a thousand feet of the shore, when in so doing the lives and health of the people were endangered.

At a clinical meeting of the Chicago Medical Society, held October 25th, Dr. Harold N. Moyer showed a case of Reynaud's disease in a man, thirty-five years of age, whose family history is free from neurotic heredity. Patient was twenty-seven years old when the present trouble began. Dr. Moyer did not consider it a typical case of this disease, as it was impossible in the description of the

patient to identify the three stages of pallor of the surface, hyperemia, and local asphyxia. In some respects the case resembled erythromelalgia. The pain was much greater than commonly occurs in Reynaud's disease, and the redness which accompanied the swelling persisted a long time preceding death of the part. The patient has had twelve attacks, covering a period of nearly eight years. In only two instances have the attacks occurred simultaneously in two parts; in every other instance the preceding attack was completely healed before the following one appeared. An interesting point was the absence of both the left and right radial pulses, due, he believes, to anatomical peculiarities entirely apart from the disease. It is, however, a significant coincidence.

Dr. L. C. Pardee showed a case presenting simultaneously the eruptions of psoriasis and dermatitis herpetiformis, each separate and distinct and uninfluenced by the other.

SPECIAL ARTICLE.

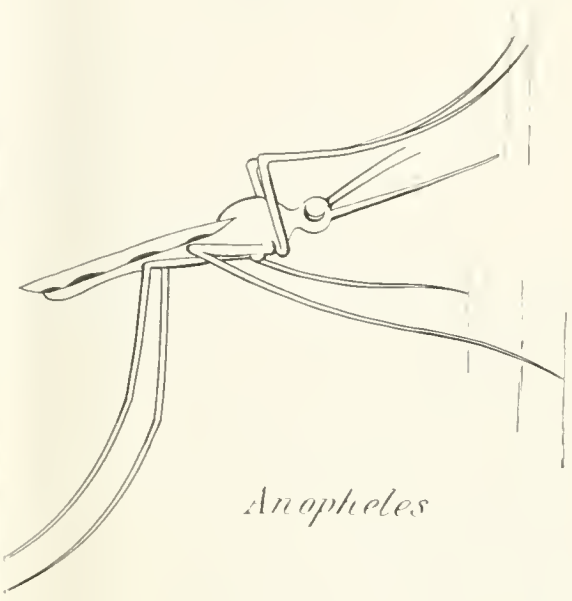
THE MALARIA-BREEDING MOSQUITO.

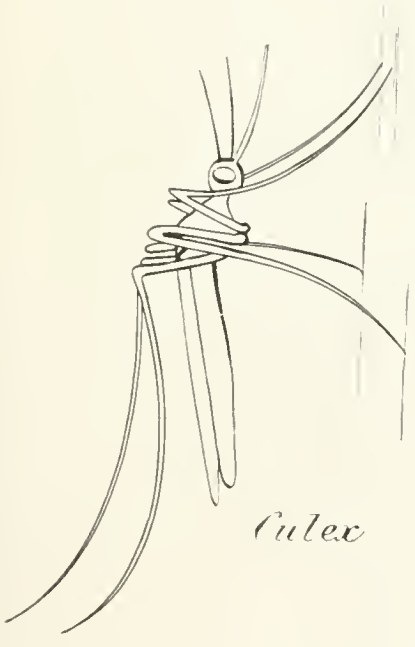
So much has been said recently about the genus mosquito which carries the malaria plasmodium that we have thought it would be of interest to our readers to know the following simple method of recognizing it. The accompanying illustrations are borrowed from the *British Medical Journal* for September 30, 1899. The easily recognizable trait of the genus *anopheles*, the only malaria bearer among the mosquitoes, is its attitude when resting on a wall. It differs in this very markedly from the genus *culex* which is the ordinary form of mosquito. The *British Medical Journal* says:

"In *anopheles* the axis of the body is almost vertical to the wall, while in *culex* it is parallel to the wall. The rough sketch above will suffice to show this. Hence any one who looks at a mosquito when it is seated—the time when it is best seen, of course—can tell at a glance to which genus it belongs. Popularly described, the tail of *anopheles* is said to "stick outwards," while that of *culex* points downward, or even a little toward the wall. In short, the *anopheles* when seated looks somewhat like a thorn affixed on a surface by the point. In *anopheles* the proboscis is directed toward the surface on which the insect happens to be; in *culex* it is directed parallel to that surface.

"Another striking difference is that in *anopheles* the wings generally have several dark spots along the anterior edge (to use popular language), while in *culex* the wings are generally plain. Ross says that this difference holds in all the mosquitoes seen by him, so that these characteristics must be pretty general. But nevertheless there are some known species of *anopheles* without spotted wings, and some known species of *culex* with them. A third difference is that in *anopheles* the proboscis appears peculiarly thick and long, giving the insect a pelican-like appearance. This is due to the palpi being held close to the proboscis."

Wherever the genus *anopheles* occurs there is danger of malaria. Other mosquitoes do not convey malaria so far as is known at present. The prophylaxis of malaria consists in getting rid of *anopheles* and protecting people against it. They bite especially at night, passing the day in a dormant state in which they may easily be caught.





Where the *anopheles* mosquito occurs, patients suffering from malaria should protect themselves from the mosquito as it is by biting them that the insect gets its store of inoculable material.

NOTABLE BOOKS.

RECENT NOTABLE BOOKS AND ARTICLES ON VACCINATION.

"VACCINATION." BY S. MONCKTON COPEMAN.[1]

"VACCINATION A DELUSION." BY ALFRED RUSSELL WALLACE.[2]

"A CENTURY OF VACCINATION." BY W. SCOTT TEBB.[3]

"THE HISTORY AND EFFECTS OF VACCINATION." *Edinburgh Review*, April, 1899.[4]

THE fact that the British Parliament thought it advisable to pass a law allowing those who had any conscientious objection to vaccination for themselves or their children to make a declaration to this effect before a magistrate and thus free themselves from the obligation of the compulsory vaccination law, has given a great impulse to vaccination literature pro and con. As to conscientious objection itself nothing better has been said than that in the new "Nox Ambrosiana" in *Blackwood's Magazine* for April.

The Shepherd (loquitur): "I wad like fine Mr. N—— to hear your defeneetion of a conscientious objector. Ma conscience gin the shepherd had his wull o them there wad na be mony sic cattle stravagning aboot the kintra-side disseminating their abominable diseases."

Kit North: "I own I have no more conception of the meaning of the word in that connection [conscientious objector to vaccination] than of the meaning of a conscientious objector to the multiplication table. I cannot, however, absolve the medical profession of all blame in the matter. Had they uttered a louder and more certain sound I believe the House of Lords at least, might have treated the bill as it deserved."

We think that these words of the illustrious North, worthily redivivus for the occasion, furnish the best reason we can give for reviewing the recent literature of vaccination. It is to be hoped that when the legislative struggle comes in this country, as come it will, if we read the signs aright, it will find a united profession which understands thoroughly the reasons for the faith that is in them as regards Jenner's great discovery.

Vaccination was introduced just a little more than one hundred years ago. It would certainly not seem too much to expect that all argument as to its utility or futility would have ceased long ere this, yet the list of works we have just quoted, which have all appeared during the last few months, seems to show that the question is still a living issue. The recent action of the British Parliament in lightening the compulsoriness of vaccination, though this was concealed behind the veil of conscientious objection to the proceedings, came as a distinct shock to the medical world. It is a good rule that *audi alteram partem*, even though one may be sure *aliunde* that the other party is wrong. It is of special interest to physicians in this case to know something of what has been said on the other side, *i.e.*, by the opponents of vaccination, because their arguments are quoted often by the non-medical public as if they were unanswerable, and it behooves one to be prepared for them. We have ventured, therefore, to throw all the important protagonists together and discuss some of their opinions where the benefit of contrasting ideas will serve to show them in their proper light.

Dr. Copeman's book is a plain matter-of-fact statement of the important points with regard to vaccination. It is not a complete treatise and will perhaps be of little value to physicians who, interested in vaccination for years, have followed more or less carefully the literature of the subject, but it is the sort of book which gives the essential facts that are so frequently the subject of discussion. As Dr. Copeman was awarded a medal for certain experimental work on the bacteriology of vaccinia, and more especially for his important practical discovery of the influence of glycerin when mixed with calf-lymph in inhibiting and finally eradicating any adventitious micro-organisms that may be present, it is evident that his work on the subject will be thoroughly up to date.

The book while in certain respects a good compilation of what has been done in vaccination is especially valuable as the record of a large amount of patient and successful original investigation. Some quotations at the beginning of the book from contemporary records serve to show how prevalent smallpox was in England before the introduction of vaccination. The following from "Pages from a Private Diary," which appeared in the *Cornhill Magazine* for January of last year shows how ever present was the thought of smallpox to the people of the prevaccination era in England. Mrs. Waller writes to her son who was in exile from England at the time and wishes to know how much dowry he is prepared to give with his daughter.

"I am not in haste to marry her," she says; "she is young enough to stay, but the danger is if she should catch smallpox and her beauty should change it would be a great loss to her."

For medical men who may have any haunting fears that Jenner's work because done a century ago was unscientific in its methods or inexact in the conclusions drawn, will find that the brief succinct review of that work by Dr. Copeman will lay all their fears in this matter. Any doubts that may exist in fair minds as to the identity of vaccinia and variola, the former being only a modification of the latter, will be laid to rest by the careful, judicious review of all the observations that have been made on this subject, especially some convincing recent experiments.

It is a distinct surprise to find a man like Mr. Alfred Russell Wallace among the antivaccinationists. He was the discoverer at the same time with Darwin of certain

[1] "Vaccination; Its Natural History and Pathology," being the Milroy Lectures for 1898, delivered before the Royal College of Physicians of London. By S. Monckton Copeman. [Work honored by a medal of the College. New York: Macmillan & Company, 1899.

[4] "The History and Effects of Vaccination." *Edinburgh Review*, April, 1899. A review of six recent books and articles on the subject of vaccination published in England.

principles of evolution, and his work since in biology has ranked him with the great scientists and thinkers of the century. When Mr. Wallace has anything to say he says it forcibly. His condemnation of vaccination is utter and unsparing. He says: "The operation is admittedly the cause of many deaths and of a large though unknown amount of permanent injury. The only really trustworthy statistics on a large scale prove it to be wholly without effect as a preventive of smallpox. It will undoubtedly rank as the greatest and most pernicious failure of the Nineteenth Century. It will be one of the inexplicable wonders of future generations that the delusion as to vaccination should have prevailed among men of science when progress in medicine was at its acme, at the close of a wonderful century of scientific discovery."

Mr. Wallace supports his position against vaccination by the usual arguments of the antivaccinationists: the decrease in the mortality from smallpox is due to the better sanitary conditions in the city and country, but not to vaccination. "Smallpox," he says, "other things being equal, is a function of density of population but pays no regard whatever to vaccination." One is sorely tempted to ask here if the population anywhere in the world 'other things being equal' has grown less dense in anything like the proportion that smallpox has become less frequent. Mr. Wallace holds up the crucial test of unvaccinated Leicester, with a very low death-rate. We note that very little is said of Gloucester whose bitter lesson of the fatal epidemic of a few years ago is a sad thorn in the side of the English antivaccinationists. The death-rate of unvaccinated Leicester from smallpox, some 15 per million, is compared triumphantly with the smallpox death-rate in the faithfully revaccinated army and navy, which is some 37 per million, but nothing is said of the much greater exposure of the army and navy to infection with the disease and that, too, very often under unfavorable conditions of climate and sanitation and hospital care.

The most telling reflections on Mr. Wallace's peculiar position with regard to vaccination are to be found in the opinions he advances on some other topics in the same book. For instance, in his essay on "The Neglect of Phrenology" he says: "In the coming century phrenology will assuredly attain general acceptance. It will prove itself to be the true science of the mind. Its practical uses in education, in self-discipline, in the reformatory treatment of criminals and in the remedial treatment of the insane will give it one of the highest places in the hierarchy of the sciences. Its persistent neglect during this last sixty years will be referred to as an example of the almost incredible narrowness and prejudice that prevailed among men of science at the very time when they were making such splendid advances in other fields of thought and discovery." Mr. Wallace stands absolutely alone among serious men of science in holding such opinions with regard to phrenology. They are on a par with his peculiar notions as to vaccination.

In his essay in the same volume on "Hypnotism and Psychical Research" he holds almost an equally extreme opinion. "Thought transference," he writes, "automatic writing, trance-speaking and clairvoyance have all been demonstrated. The still more extraordinary phenomena of 'veridical hallucinations,' warnings, detailed prediction of future events, phantoms, voices, or knockings visible or audible to numbers of individuals, bell-ringing, stone-throwing without visible human agency still occur as they have in all ages."

It is not necessary to comment further on the author's peculiar position as to vaccination. If anything more were needed it will be found in some reflections on his facts and statistics which we shall quote from the last of the articles on vaccination that we review in this article.

Dr. Tebb is one of the great leaders of the antivaccinationists in England. His book is an attempt to show that vaccination has never accomplished the slightest good and as it has at times done harm in various ways, by syphilitic inoculations, by lighting up erysipelas and the like, that it should be entirely abandoned. The book is a magnificent example of special pleading, written in an assumed temper of the most guileless impartiality, yet it takes but very little consideration to detect the ineradicable prejudice that has animated the writer in his every look at the subject. Appeals to popular feeling are most skilfully made by the publication of every fact that has found a place in medical literature during the century that can be made in any way to tell or seem to tell against vaccination. A number of instances from the beginning of the century in which vaccination did not protect are quoted in detail. Not a word is said of the fact that defective technic sometimes led to apparent but not real vaccination in those early days. There might be a scar due to certain germs inoculated at the same time with the supposed vaccine virus and yet the patient may not really have had vaccinia at all and consequently not have had the benefit of its protection.

A great deal is made of the various epidemics of syphilis due to the use of humanized virus taken from the persons of patients suffering from syphilis. Owing to the way in which the matter is treated the impression can scarcely fail to be left on the minds of lay readers that such epidemics are also liable to occur now. In fact Dr. Tebb deliberately and explicitly says that "there is no guarantee that syphilis or symptoms indistinguishable from this malady may not be induced by the inoculation of either human or *animal* virus." As we know absolutely no animal, least of all any of the herbivora, which is liable to syphilis the indefensible position Dr. Tebb takes is evident.

It is only a sample, though, of the methods used throughout the book to sway the unthinking to his views. All the cases of leprosy that have ever occurred as the result of vaccination with vaccine lymph from lepers are quoted in minutest detail. The total of these is not very great but the lay reader by implication is worked up to think that perhaps the communication of leprosy by vaccine lymph is possible even in countries in which the disease does not exist.

As a good model of special pleading Dr. Tebb's work can be recommended without scruple to all those whose purpose in life is that of making the worse appear the

better part. That great purpose of the sophists of old is accomplished with a skill that even the most acute of Greek dialecticians would have envied. It would require the trenchant pen of Aristophanes to properly characterize it.

The article in the April number of the *Edinburgh Review*, on the "History and Effects of Vaccination" ought to prove a good antidote to some of the dangerous matter that has found its way into circulation as a consequence of the recent agitation over the Conscientious Objection bill in England. It contains especially an excellent discussion of "Sanitation and Isolation," the watchwords of the antivaccinationists. Sanitation and isolation, according to the opponents of vaccination, have accomplished all that has been done to limit smallpox in the past and will practically eradicate it in the future. It is pointed out by the writer in the *Edinburgh Review* that smallpox does not originate in filthy surroundings, and that, if introduced it may become epidemic in the most hygienic of country districts or in well-regulated towns. As for perfect isolation for smallpox it is an illusion. Before the disease has become distinct enough for diagnosis and yet while it is undoubtedly contagious, intercourse with healthy ndividuals is inevitable. It is vaccination that has reduced the mortality from smallpox during the present century and the hope for the ultimate eradication of the disease lies in this direction.

As to the danger from vaccination the last set of statistics carefully compiled in Germany shows one death to 100,000 vaccinations, delicate children especially being subjects of even this extremely small mortality. This mortality is not due so much to vaccinia itself as to complications. The inoculation of other infectious material with the vaccine matter has been the principal cause. Now that the use of vaccine lymph which has been kept in glycerin without access of light and air for some time practically assures absolutely uncontaminated vaccine material even this death-rate will be lessened.

We may close with a citation from Dr. McVail's "Vaccination Vindicated" which the writer in the *Edinburgh Review* quotes: "Dr. McVail refers to the statements of Mr. Alfred Russell Wallace and exposes an amount of inaccuracy in assertion and statistics that is amazing and lamentable and says: 'The rule is to believe no single word that an antivaccinationist as such says without obtaining independent evidence of the truth of his assertions. No matter what the position or absolute trustworthiness of the person in every other relation of life, yet when he comes to write on this subject his every statement demands the most rigid scrutiny.'"

A New Application of the Roentgen-Rays —The most recent application of the Röntgen-rays is in the study of what may be called prehistoric zoology. Skiagraphs of the mummied animals in the British Museum have been taken on a large scale for the purpose of comparing the skeletons of the sacred monkeys, etc., with those of existing species. Several curious resemblances and some striking differences have already been made out in this study.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE OPEN-AIR TREATMENT IN LONDON—TIDE OF LONDON MEDICAL STUDENTS TO THE TRANSVAAL—TWO NEW HOSPITAL SHIPS FOR SOUTH AFRICA—OPENING OF THE SCHOOL OF TROPICAL MEDICINE—DR. PATRICK MANSON'S "POLICY OF THE RAT-TRAP"—POSITION OF MEDICAL WOMEN IN LONDON—FILTHINESS OF OPORTO—MEETINGS AND METHODS OF LONDON MEDICAL SOCIETIES—POST-GRADUATE WORK IN LONDON—INDEPENDENCE OF HOSPITAL PATIENTS.

LONDON, OCTOBER 22, 1899.

THE report of the Medical Registrar of the North London Hospital for Consumption at Hamstead, which appeared last week is a most encouraging document. Of 183 patients treated since January last no less than 43.7 per cent. have left the hospital apparently cured and returned to work and of these none who has continued to follow out the methods of living and diet in which he was carefully instructed has as yet relapsed. Distinct improvement occurred in 32.3 per cent. additional patients and slight improvements in 7.6 per cent. About 14 per cent. failed to improve and 4 per cent. died. If results like this can be secured on the edge of and often actually in the fogs and damps of London, every city should certainly have its municipal sanatorium.

The horrors of war are already being experienced with surprising promptness in the most unexpected quarter of the profession, and that is in the London post-graduate schools. The Army Medical Department is so short-handed that not only have nearly all the medical officers been either recalled to duty or detailed for South Africa, but quite a considerable number of the class of younger medical visitors to London, intending to take special hospital work, has been attracted by the opportunity for experience and adventure offered by service in South Africa. It is certainly not the salary that attracts them, for that appears to range only from about $1400 to $1800 a year. Altogether the effect on the London schools depending largely on post-graduate students, such as the Polyclinic, West London, and School of Tropical Medicine has been extremely disastrous. Some of them have lost as many as twelve or fifteen entered students from this cause alone. Professor Ogston's prognostications at the Portsmouth meeting seem to be coming true to the letter already, as the Army Department finds itself so extremely short-handed that its first step is to issue a call for civilian medical volunteers. In spite of the small salary we understand this has been promptly and largely responded to.

Another medical preparation for the contingencies in the Transvaal is of a more gratifying character, in the shape of two hospital-ships which have been specially fitted up for this emergency. Two Union Cape liners, "Spartan" and "Trojan", have been chartered for the purpose, and one of them has already been turned into an admirable floating hospital equipped with the latest electric fans for ventilation, sixty-five swing-cots so ar-

ranged that they can sway with the motion of the vessel or be locked absolutely steady, sisters' quarters and medical-officers' quarters. A most important part of the equipment, of the need of which in tropical warfare our terrible experience before Santiago served as a magnificent object-lesson to the civilized world, is a hugh carbon dioxid refrigerating-machine capable of turning out half a ton of ice per day. The operating-room is placed in a superstructure on the upper deck and is beautifully fitted up with the latest mechanism in operating-tables. A complete Röntgen-ray apparatus for the localization of bullets finishes this almost ideal equipment. As the heaviest part of the fighting is expected to occur from within sixty to a hundred miles of the coast a floating hospital of this description in the sea air will be a perfect godsend to many a poor fellow in the stream of wounded pouring back from the front.

The School of Tropical Medicine opened last week with a small, but in view of the terrible depletion of post-graduate London already referred to, a fairly satisfactory attendance. As this school, which expects to draw chiefly from Colonial medical officers, many of whom have been recalled to their posts, in addition to the army medical men, it can hardly be expected that its first attendance will reach any very considerable figure until the present war tension is removed.

Among the addresses that were delivered at the opening of the hospitals recently three have attracted general attention, not merely in the profession but in the daily press. First of these was the admirable address of Dr. Patrick Manson, at the opening of the School of Tropical Medicine, in which he graphically depicted the great public and professional advances which were to be hoped for from the newly opened campaign against the plagues of the tropics. His epigrammatic characterization of the fight against the bubonic plague, malaria, and the cholera as a campaign of the rat-trap, the mosquito-net, and the tea-kettle, was an admirable one and has stuck in the popular mind. He said that for fifteen years past he had been coming more and more to suspect the rat as the sole vehicle of contagion from one human being and from one epidemic to another in the case of bubonic plague and that the recent reports of the Plague Commission had more than sustained his pioneer position. His studies upon filariasis had led him to much the same conclusion in regard to malaria. As to cholera, it was agreed on all hands that its only vehicle is the drinking-water, and that by boiling or filtering this practical immunity could be secured, although it is earnestly to be hoped that a wider-reaching and earlier method of breaking the fatal chain of infection will be discovered ere long.

The second address which attracted special attention was that of Professor Sims Woodhead of Cambridge before the Royal Veterinary College, which all regard as an encouraging omen of the closer relations which are continually being established between the human and the veterinary practitioner, and in which each will be strengthening the hands of the other so immensely in both the study and the prevention of disease.

The third was the witty address of Dr. Garrett Anderson at the opening of the London School of Medicine for Women, which derived special importance from the fact of their entering upon the use of at least a portion of their fine new building. Dr. Anderson took the wise, and under the circumstances, the philosophic position that for the present at least a school for women only is to be regarded as preferable to an attempt to secure a mixed school. The prospects in London in the last respect are not at all as much superior to those of ten years ago as one would wish. None of the great medical hospital schools and comparatively few of the great hospitals will admit women either to their teaching or practice, and even post-graduate institutions like the Polyclinic find themselves compelled by the opposition of patients and of the mass of their male students to content themselves with trying to form separate classes and clinical demonstrations for women students alone. The objection to women physicians as such has unquestionably softened down greatly both in the profession and in the community, but at the same time there appears, to an American at least, a positively ludicrous dread on the part both of the undergraduate and the post-graduate medical student of meeting women in classes, lectures, or clinics

Medical experts have for the most part vigorously contended all through the recent, but we trust now diminishing, plague scare, that the bubonic plague could practically find no footing in any part of *civilized* Europe and now comes a full report of the state of affairs at Oporto which abundantly explains how the plague succeeded in getting its extremely insecure and slight foothold in a city which was supposed to be civilized. This cheerful town has the fourth highest death-rate in Europe, no water-supply to speak of, no regular system of drainage or of disposing of refuse, and its poorer classes live twelve or more in one room. The poverty of the people is abject, the average wage is about thirty cents a day, and the diet salt codfish and potatoes. If a patch of soil had been prepared and fertilized, warmed and watered all with special reference to growing a magnificent crop of the plague this could hardly have been improved upon, and yet the condition is, with all these shameful defects, so much superior to the present state of affairs in the Orient and to the European condition in the Middle Ages, that the plague is barely holding its own and has not spread a mile in any direction outside of the town. A city conscious of clean streets, good sewage and good water-supply can have the peace which comes from the proverbial "*mens conscia recti*" with regard to danger from the plague.

A second step in the opening of the medical year in London, the meeting of the great medical societies, was taken last week. Many of these open with a formal address followed by a *conversazione*. Dr. Frederick Roberts opened the year of the Medical Society of London by an address on "Personal Experience in Relation to Serum Therapeutics and Antitoxin Treatment." Dr. Sanson presided at the Hunterian Society and delivered an address on "The Effects of Influenza on the Heart and Circulation," while the British Gynecological Society and the Clinical Society of London had their opening meet-

ings with a regular program of papers. The medica visitor to London may at first find himself under some little feeling of embarrassment in regard to attending these society meetings, inasmuch as the name of some member is required as an introducer, but this can easily be secured by writing to any member who is to read a paper in which the visitor is interested, and indeed for a single visit the president and secretary usually leave instructions with the porter at the door to use their names for the introduction of any *bona fide* medical visitor who may come in on the evening of the meeting. Although the attendance at these meetings will not be found at all as large as would be hoped in a great city like London, yet their proceedings are usually of great interest and well illustrated with specimens, drawings, and actual cases. While some of the societies meet in widely separated regions, yet a very considerable proportion of the larger and more important ones hold their sessions in Chandos street opposite the Langham Hotel, in the building of the Medical Society of London, or in the rooms of the Royal Medical-Chirurgical Society in Hanover Square, both within a few hundred yards of Oxford Circus.

A very interesting course of weekly lectures, free to medical practitioners and senior students, on diseases of the nervous system, will be conducted during the winter on Tuesday afternoons at Queen's Square Hospital by various members of the staff. Another course of much interest to visiting medical men is to be given on Thursdays at the Hospital for Sick Children, Great Ormond street, by the staff. For this a small fee is charged. What with such courses as these in the different special hospitals and with the wide choice of courses, both more general and supplementary in character, offered by the Polyclinic and the West London Post-Graduate School, the position of the visiting medical post-graduate student in London is greatly improved and improving. Courses can now be obtained in almost any special subject from bacteriology through all the clinical "ologies" to the use of the Röntgen-rays, and although these are not yet centralized to any such desirable degree as have been effected in the great Continental medical centers yet the tide is setting steadily in that direction. A considerable degree of fusion of this description has already been accomplished by the Polyclinic and when the teaching University of London adds its powerful impulse to the others already in operation there can be little question that a great centralized scheme of post-graduate teaching and probably a great central teaching institution will grow up which will put London upon the same plane with Vienna, Berlin, and Paris as a medical Mecca.

One great obstacle to this scheme of centralizing at least the clinical part of medical teaching exists in the nature of the situation, and is not always perhaps appreciated at its full value. This is the intensely individualistic character which pervades not only all English institutions but all classes of English society, and is strikingly illustrated in the fact of there being eight self-supporting and totally independent medical schools instead of one central State-supported and regulated University, as in Berlin or Leipzig, and there will naturally be a distinct amount of friction before these can be got to fuse their differences in a common scheme. On the other hand, the patient himself is unfortunately more individualistic, in the widest and most aggressive sense, than his French or German brother. He will go to the hospital that he chooses in the first place and distinctly refuse to budge to another no matter what inducements may be offered him in the way of superior advice, and he will object to being seen by strange doctors and strange students. He will absolutely refuse to be operated upon unless the procedure commends itself to his individual judgment; his relatives after his death will bitterly oppose the use of his remains for post-mortem study, and in a score of other ways he is often a serious practical obstacle in the way of systematic clinical work. Nor does he stand alone in this, for it may never be forgotten that all English hospitals are organized for the benefit of their patients first and foremost, and it is often with the greatest difficulty that even the staff of the hospital can get permission to use its inmates for clinical purposes within its own walls. Any complaint of unnecessarily frequent or prolonged examination on the part of the patient or of fatigue in being transported to another lecture-room, or even of outraged modesty from being submitted to the gaze of a large audience of students, will be promptly taken up and supported not merely by the Board of Governors of the hospital but also by the outside public upon whose voluntary contributions the institution in most cases absolutely depends. However, and happily, both patients, Governors, and the laity are coming to recognize the true value and advantage of expert opinion and additional advice. The more intelligent class of patients is coming to respond readily to any suggestions as to methods of obtaining more light upon their cases. The Governors are finding that the hospital that does the best and most effective teaching also does far the best and most effective therapeutic work and the whole feeling of even the more ignorant class of the laity toward the profession is improving most pleasantly. There can be no question that both this sort of feeling on the patient's part and its frank and manly recognition on the part of the operator and consultant has a most valuable influence in keeping English and American hospital practice upon the highest plane of humanity, of courtesy, and in the broadest sense of true science than that which obtains in some Continental centers.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSSOCIATION.

Sixteenth Annual Meeting, Held at the New York Academy of Medicine, New York City, October 24, 25, and 26, 1899.

First Day—October 24th.

Morning Session.

The President, Dr. Joseph D. Bryant of New York City delivered the president's annual address. Its title was

THE INFLUENCE OF MEDICAL PRACTICE UPON MEDICAL PROGRESS.

He said in brief : The practice of medicine, it must be borne in mind, should be a means of education and advance for the medical profession. There is somehow an impression that what we learn at school is the important part of our education, but this is by no means true. Medicine is an art as yet rather than a science, and it is actual practice in an art that makes its devotees efficient in its employment. The history of medicine shows that it is always considerations drawn from practice rather than from theory that have done most for the development of its possibilities for doing good.

The practice of medicine has always been a very serious profession. The first doctors were the priests, and it was among the priestly class in India that the foundations of the healing art were laid. The first medical document that we possess, the papyrus of Ebers, from about 1550 before Christ, shows that in Egypt the same thing was true. Great advances have been made, but it has only been by seriously realizing how much the practical side of medical science has done for its development. In our own day medical advances have been of so much importance that we have learned to lessen the amount especially of contagious disease and to diminish human suffering. There is even a vista opening up of a future in which many of the ailments that used to afflict mankind will be absent. We cannot get rid of all suffering, and until we have discovered and isolated and secured the antitoxin of the bacillus of old age we will not be able to get rid of senility and death. Meantime, however, we must remember that "every addition to true knowledge," as Mann said, "is an addition to human power" ; that every discovery in medical science should have its practical application. Medical-society meetings are especially useful to enable us to realize the practical application of new discoveries in medicine and, besides, to enable us to realize whether we are really serving the cause of humanity, or really personal ends. No true and adequate value can be placed on medical care. A physician's services cannot be adequately rewarded. This furnishes all the more reason for us to shun venal practice and sordid ideals. Medical society meetings prompt us to examine our medical consciences, to find out whether we are living up to our dignity as members of an honorable profession. Such meditation is healthy and healthgiving in its effects. Its periodical recurrence cannot but be of benefit to us so that these meetings have a value quite apart from the additions they may furnish to our scientific knowledge. Knowledge is the hill that few may hope to climb, but duty is the path that all must tread.

Dr. Wickes Washburn presented the report of the Committee on Charities and Public Health. He detailed the efforts that had been necessary to secure the passage of the dispensary bill. He reminded the members of the Association that now it is their duty to help in the enforcement of the law. That it would be of great benefit to the medical profession is clear, but it must not be allowed to become a dead letter. He then called attention to the suggestions that had been made by the Committee on Charities in order to secure the enforcement of the law, and asked that members take an interest in the matter.

DR. THOMAS J. HILLIS of New York County then read a paper, entitled

ALCOHOL AS A STIMULANT AND HEART TONIC ; ITS USE TO THE ANIMAL ECONOMY IN HEALTH AND DISEASE.

He said that, until recently, we have had very little definite information as to the medical properties of alcohol. There has been a good deal of talk, mostly come from those who are fanatically opposed to its use, and every good effect has been denied to it. Some even went so far as to say that it is not a stimulant. Not long ago Professor Atwater showed that it is used by the system as a food. There is no doubt that in various allotropic modifications which it undergoes in the chemical laboratory of the body it develops many other properties beyond that of stimulation. It is a tonic, heat-producing food of the most valuable kind. It has been abused and will be abused, but the abuse of a thing cannot logically be argued against the proper use of it.

It is in conditions of fatigue particularly that alcohol is of special service. It is much better than coffee and produces its effect more rapidly. When great fatigue exists it is promptly burned up in the body and does not produce its ordinary intoxicating effect. Under these conditions 8 to 10 ounces of it even may be taken and produce only slight stimulation. Like shavings in a glass furnace, it is burnt up by the fire of muscular metabolism. Much of the abuse of alcohol by the medical profession has come from the fact that it has been given too early or too late in the course of a disease, or that too much or too little of it has been given. Its administration must not be left to the nurse, but must be assumed by the doctor himself. It must be regulated not according to any fixed rule, but according to the effect produced upon the patient.

The primary factor in the matter is the stomach. If the stomach takes food well, then alcohol is not needed, but when food cannot be taken, alcohol is of the greatest service. Especially it must never be given if it disturbs the stomach. One day it may be poison in a given case and the next day it may do good. Alcohol should never be taken at the beginning of a journey, for it lowers the temperature and increases the tendency to fatigue. At the end of a journey it is usually of very great service. At the beginning of diseases that are accompanied by excitement it will do harm. In exhausted conditions of the patient, especially when nutriment is not taken well, it is of the greatest service. It acts in four minutes, while beef-tea requires twenty to act and is not as efficient. Alcohol should never be taken immediately after meals, for it paralyzes the digestive ferment, coagulates the albuminoids, relaxes the walls of the stomach, and may stop the process of digestion entirely. Three hours after digestion, especially if the fatty acids are

present, causing the condition known as pyrosis, alcohol will neutralize the fatty acids, stimulate the peristaltic action of the stomach, and get rid of the uncomfortable feeling.

In the discussion which followed the reading of the paper, DR. DIDAMA of Syracuse said that alcohol is not his sheet-anchor in practice; in fact, that he had not used it at all during the last five years, and while he does not find fault with those who use it carefully, he thought that it can easily be replaced in therapeutics by drugs that do not possess its dangerous qualities.

DR. MARCY of Boston said that while acting as a surgeon during the Civil War he had found that twenty-minutes' rest with a cup of coffee was a good deal better for fatigued soldiers than a ration of whisky.

In closing the discussion, DR. HILLIS said that alcohol is under all circumstances the best tonic that we have, and that for it we should sacrifice willingly most of the drugs of the pharmacopœia.

The next paper was read by DR. WICKES WASHBURN of New York County, and was entitled

THE NECESSITY FOR EXACT EVIDENCE IN TREATING SCIENTIFIC SUBJECTS.

He presented some examples of how easy it is to be deceived in medical matters, and made a plea for more exact observation. Tubercle bacilli, after all, may be found in healthy persons. The germs float in the air and sometimes find their way into the air-passages as a consequence. They may exist there for some time without producing disease, and may be thrown off in the secretions. It must not be concluded, after a single observation, then, that a person has tuberculosis. The true scientific spirit would dictate that further examinations should be made. The same thing holds true for diphtheria. The germ of the disease has been found in healthy throats. The streptococcus has been found in the healthy urethra, yet without producing any symptoms. In these cases it is evident that the matter of a suitable soil is a very important question before these micro-organisms produce any pathological changes. These and like facts show how necessary it is to carefully weigh evidence before coming to conclusions in medicine.

The paper of DR. HENRY W. WANDLESS of New York County, "The Correction of Irregularities of the Nasal Septum and the Exhibition of New Instruments," was read by title.

DR. FRANK OVERTON of Suffolk County then read a paper, entitled

THE PHYSICIAN AS A FACTOR IN EDUCATION.

Dr. Oliver Wendell Holmes once said that every man is a trinity. He is what he thinks himself to be, what others think him to be, and what he really is. The duty of self-development requires that as far as possible what a man thinks he is and what he really is should be the same. In this matter physicians owe a duty to their patients in enabling them to get rid of certain false notions that all of us seem to imbibe by a sort of tradition, for knowledge is as much a tradition now as it was in Homer's time. Medical tradition, especially, is composed of a body of knowledge that everybody thinks he possesses, and that contains some most peculiar antique notions. As the result of this tradition doctors are continually being asked the most bizarre questions. Many physicians seem to think that they should not entirely disagree with their patients, but should rather model their answers on the knowledge the patient supposes himself to be possessed of. This, however, is a mistake, and it leads to a perpetuation of the most erroneous ideas. A great deal of good can be done by explaining simply, yet scientifically, the nature of certain things about which the patient's curiosity has been aroused. The nature of infectious diseases may be explained, and the possibility of harm that lurks in such infecting material as comes from abscesses or purulent discharges or infected wounds. In nervous patients simple information may be made a means of suggestion that will greatly help in the management of these patients.

OPERATIVE TREATMENT OF HIGH MYOPIA BY REMOVAL OF THE CRYSTALLINE LENS,

was the title of a paper by DR. CHARLES STEDMAN BULL of New York County.

Shortsightedness is the scourge of modern civilization. It has really set a limit to the usefulness of education, and is a menace to modern educational methods so that our standards for entrance to public schools will have to be altered. When progressive in young children, causing degenerative changes in the choroid and retina, and when it is of more than twelve to fourteen diopters, so that it makes the images small and blurred on the retina, even when proper correcting glasses are used, it is one of the most important affections with which the ophthalmologist has to deal. A number of operative procedures have been suggested for its relief. With the idea that it results from the pressure exerted by the external muscles of the eye tenotomies were performed at one time. One surgeon suggested the cutting out of a small piece of the cornea. Baer, in 1817, first suggested the removal of the lens. This operation was opposed by Von Graeffe, who thought that it would not stop the development of the myopia. Dunders considered the removal of the lens as little short of criminal. Of late years a great change has come over medical opinion in this matter, and now most of the authorities consider that the lens should be removed if the myopia is above sixteen diopters. It is the fad just now to laud the benefits to be derived from the operation. Knapp said a very good thing with regard to the subject long ago: "The real value of the operation will only be known when the present boom for it has passed."

There are certain dangers in the operation. First, hemorrhage; second, detachment of the retina; third, the development of secondary glaucoma; fourth, infection. The fourth may be dismissed at once with our present methods of aseptic surgery. The first and second may be much lessened by attention in the selection of cases for operation. The symptoms of glaucoma, if they develop, may be relieved by removing the lens, and any of the lenticular matter which may have escaped into

the anterior chamber. As in all such operations, of course, there is some danger of prolapse of the iris, but this can be obviated, and if the iris actually prolapses excision should be performed.

The contraindications for the operation are: Degeneration of the retina and choroid in the region of the macula; the existence of any detachment of the retina; membranous opacities in the vitreous; previous loss of one eye; lack of transparency in the cornea; the existence of any infectious disease of the conjunctiva, especially of trachoma; and, finally, advanced age. The operation should not be performed if there is less than twelve diopters of error of vision. It should not be done unless the use of strong glasses will not enable the patient to carry on his work, or unless there is true progressive mpopia. The operation should never be completed at one sitting. The anterior layer of the capsule of the lens should be lacerated, and the aqueous humor allowed to dissolve the lenticular matter. In young patients no further operation will be necessary. In older patients, should symptoms of glaucoma develop, the lens must be removed.

AFTERNOON SESSION.

DR. F. O. DONOHUE of Onandaga County read a paper, entitled

PROGRESS OF THE SCIENCE AND ART OF OBSTETRICS.

Since the days when Sir James Simpson removed some of the terrors of childbirth by the discovery of chloroform, and Semmelweis most of its dangers by the discovery of the infectious nature of puerperal fever, obstetrics has gone steadily forward until now it is one of the most advanced of the medical sciences. Especially in its conservatism have advances come in recent years. It is no longer considered justifiable to take the child's life, practically under any circumstances. Where the general mortality from Cæsarian section was ninety per cent., it is now less than nine per cent. Sanger's adaptation of the Lembert suture to the uterus is responsible for a good deal of this change, though of course a great deal of it is due to modern aseptic methods. In general childbearing has lost practically all of its terrors. What is needed now is that every physician should perfect himself in the great art of midwifery.

In the discussion DR. W. E. SWAN of Saratoga Springs said that modern discoveries are bringing us to the solution of the questions involved in that great scourge of humanity. puerperal fever. We are learning to recognize the micro-organisms that cause it. The staphylococcus has been found, and the streptococcus and in at least one case the typhoid bacillus. The treatment for these conditions is very different. Staphylococci always exist near the surface and can be removed with a dull curette and plentiful use of salt solution. The streptococcus always occurs deep in the uterine tissue and the use of the curette is not advisable. It may even do harm. It is important then that a careful investigation should be made by bacteriological methods in order to decide the pathogenic agent that is at work.

DR. RICH of Brooklyn said that not more than one finger should be used in making examinations before labor. The air also contains pathogenic germs and its admission is a source of danger. This can be avoided by the method of examination he suggests.

DR. DOUGLAS AYRES of Montgomery County read a paper, entitled

SOME PRACTICAL EXPERIENCE IN ASEPSIS AND ANTISEPSIS IN OBSTETRICS.

Physicians do not sufficiently realize how important is asepsis in obstetrical practice. It is to be remembered that 1¾ per cent. of all deaths take place from various causes during the puerperal period. In Germany statistics seem to show that 10 to 15 per cent. of the deaths in women during the period of sexual activity are due to causes connected with pregnancy. A good many of these deaths are due to chance infection during the puerperal period. No doctor should attend a woman in labor who is attending cases of any of the infectious fevers, or who is occupied in treating abscesses, or affections involving purulent discharges. It must be remembered that especially the hair and the beard are liable to carry germs of infection. Therefore, these should be carefully washed. The most elaborate precaution should be taken in the matter of bathing, etc.

The paper of DR. CHARLES H. GLIDDEN of Herkimer County, entitled

A REPORT OF A CASE OF PUERPERAL SEPSIS AND WHAT IT TEACHES,

will be published in a subsequent number of the MEDICAL NEWS.

DR. FREDERICK S. COWLES of Westbrook, Conn., read a paper, entitled

HYDRORRHEA AND HYDROSALPINX.

He described a case in which at the sixth month of pregnancy there had been an escape of fluid from the uterus but no blood. Abortion was feared but plenty of fluid remained in the uterus as ballottement could be practised. Several such attacks followed at intervals of several weeks and yet a healthy child was born at full term. Two months after labor the speaker was summoned to see the patient. He found her in severe pain that at first was referred to the umbilicus, and afterward was localized in the right iliac fossa. Her pulse was 110, and her temperature 102° F. The abdomen was tender and there was considerable tympanites. He applied an ice-bag and gave calomel and a saline. He suspected appendicitis and his suspicions were confirmed by a surgeon whom he called in consultation. The woman herself said that she felt very much as if she were going to have one of the discharges she had had during her pregnancy. This proved to be the case and the gush of fluid relieved the pain, while the other symptoms gradually disappeared. She had subsequent attacks of the same kind, each of them occurring about a week before her menses.

The source of hydrorrhea in this case would seem to be the tube and the condition to be a hydrosalpingitis. The condition is more frequent than is thought and its differ-

entiation from appendicitis makes it important. It is evident that in obscure cases which are diagnosed as appendicitis an examination per vaginam is very necessary.

DR. MAX EINHORN of New York County read a paper, entitled

A BRIEF SUMMARY OF THE INDICATIONS FOR OPERATIONS ON THE STOMACH.

It will appear in a subsequent issue of the MEDICAL NEWS.

DR. W. B. REID of Oneida County then read a paper, entitled

THE VALUE OF OPERATIVE TREATMENT FOR SPINA BIFIDA.

In a case in which the tumor was the size of a large orange and in which the arches of the second, third, and fourth lumbar vertebræ were absent he removed the tumor two years ago, raising the periosteum of the vertebræ and succeeding in getting the periosteal flaps to cover the defect. The child was then put in a plaster jacket with a window over the site of operation. Ten weeks after the operation there was a bony callus to be felt at the spot, and at the end of fifteen weeks firm bone had formed. More than two years have elapsed and the child is perfectly healthy.

In this case pressure on the sac of the tumor caused the evacuation of part of its contents, and at the same time the fontanels became tense. It used to be said that this was a contraindication to operation for spina bifida, but the success in the present case shows it is not. The London Clinical Society, after an investigation of the subject fifteen years ago, decided that the injection of the sac of spina bifida with iodin is the best means of treatment. With our modern advances in asepsis a radical operation would seem to be indicated. The danger of fatal collapse from sudden relief of pressure on the brain may be obviated as in this case by repeated tappings of the tumor with a hypodermic needle.

DR. JOHN A. FORDYCE of New York County followed with a paper, entitled

SOME CUTANEOUS MANIFESTATIONS OF SYPHILIS AND OTHER AFFECTIONS OF THE SKIN, ILLUSTRATED BY LANTERN-SLIDES.

He began by the exhibition of slides of cases of chancres on the lips, and for comparative purposes several labial epitheliomata. He pointed out that the more rapid course of the chancre and the therapeutic test besides the appearance are the important diagnostic differentials. By a number of slides he showed that where the secondary lesions of syphilis had been most marked, that there too, the subsequent lesions were likely to be most severe. One case exhibited, an extremely painful ulcer very obstinate to treatment, had developed over the sternum seemingly without external cause. The patient had had interstitial keratitis, and had the notched incisors characteristic of congenital syphilis so that the ulcer was diagnosed as due to hereditary syphilis and yielded to specific treatment. A number of cases of lichen planus were shown in which the extent of the cutaneous lesions and their symmetrical arrangement might at first cause one to think of syphilis. A case of syphilis in a woman with nephritis was shown. She did not bear mercury and the iodids well and an intense pigmentation had remained after the slow disappearance of the cutaneous lesions. At the end of two years some of this pigmentation still remained. Often in cases of nephritis salivation set in early and treatment became a difficult matter. The skin and bowels in such cases must be made to do active eliminative work.

SECOND DAY—OCTOBER 25TH.

MORNING SESSION.

DR. GEORGE W. GOLER of Monroe County read a paper, entitled

THE NECESSITY FOR STATE AID IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

Thirteen thousand cases of death from tuberculosis took place in New York State during the last year. Counting an average of one death to every four cases there were altogether over fifty thousand cases of tuberculosis within the commonwealth. At least one-fourth of these patients could have been cured, for the statistics of the best sanatoria show more than this proportion of cures. New York State owes it to its citizens to protect them from the dissemination of the disease and to prevent as far as possible the present mortality. The State now spends seven millions on the insane. No one would think of disputing the advisability of State aid in the treatment and handling of lunatics. Of late the care of epileptics also has come under State control. The result has been eminently satisfactory and the present aid will be continued and extended. State sanatoria for tuberculosis will accomplish even more good than does the State care of the insane and of epileptics. As a matter of fact, the expenditure of a comparatively small amount of money, it can be easily demonstrated, would save to the State every year immense sums of money in the health and strength of its citizens.

SANATORIUM TREATMENT AT HOME FOR PATIENTS SUFFERING FROM PULMONARY TUBERCULOSIS

was the title of the next paper, read by DR. S. A. KNOPF of New York County.

There is no doubt left now that sanatorium treatment is the ideal therapeusis for consumption. Unfortunately not all our patients can go to sanatoria. For these it is possible to institute the sanatorium treatment at home. The features of the sanatorium treatment that are of importance are the absolute regulation of the patient's life, the freedom from reinfection by care of the sputa, the spending of long hours in the open air, and the careful regulation of diet and exercise. Most of these things can be carried out at home, not so satisfactorily, perhaps, as in a sanatorium, but still with wonderful results. Tuberculous patients should be taught at once the infectiousness of their sputa, not only for others, but especially for themselves. If the danger of reinfecting themselves is insisted on their selfishness will do more to make

them keep the regulations suggested than any altruistic feeling for others.

The sputum should be received always in vessels especially designed for it. Small aluminum cups that do not look like cuspidors may beprovided for the sick room, and should have some solution in them. Vinegar is not a bad agent to employ to neutralize bacterial virulence. Patients when out of the house should not spit in handkerchiefs, but, if they can be persuaded, either in a special flask that they carry with them or in special Japanese handkerchiefs made of paper, which can be burned immediately on their return home. These handkerchiefs should not be kept in an ordinary pocket, but in one lined with rubber, or in some rubber receptacle that can be thoroughly cleaned. All tuberculous patients should be warned to wash their hands thoroughly before eating. All linen that has been worn by consumptives should at once be put to soak and boiling water should be poured over it as soon as possible.

It is advisable that consumptive patients should have their own eating utensils. But if not, at least all such articles should be thoroughly cleansed in boiling water before being used by anybody else. All kissing, especially on the mouth, should be forbidden. During cough and loud talking tuberculous patients project minute quantities of saliva in which tubercle bacilli have been been demonstrated. They should therefore be warned at such times to keep a handkerchief before their mouths. Nurses and members of the family should be warned not to be in too close proximity to patients while they are coughing or talking. Men should not wear heavy moustaches, as they gather the bacilli and may become sources of infection to others and of reinfection to themselves.

Diet is very important. Anorexia yields better very often to the culinary art than to drugs. Patients often have caprices of appetite especially with regard to such important articles of diet as milk and eggs that may be overcome by persuasion or by careful preparation of the articles in question. Raw-scraped meat pulp is a most important addition to the diet. When the yolk of a raw egg can be taken with it, the two together constitute an ideally concentrated nourishment. To milk a small amount of bicarbonate of soda and also a small amount of salt may be added with advantage, both as regards its appetizingness and its digestibility. Patients should eat their heartiest meal at the hour of the day when their temperature is lowest.

Respiratory exercises are very good for tuberculous patients. They should breathe deeply as often as they think of it, and take regular respiratory exercises every hour, or even every half hour when they feel well. Patients should practically live in the open air. If a garden is attached to the house in that, if not, on a balcony, on the roof, on a fire-escape, or barring all these close to a window. Cold weather is no contraindication to sitting out in the cold if the patient is well wrapped up. As to exercise, patients may be advised to walk, but only if it does not cause rise in their temperature. The temperature should be taken before and after the walk. Tachycardia is also a contraindication. When exercise is taken it should be during the apyretic stage.

Hydrotherapy is very important. A douche may be given over the apices of the lungs or along the side of the lungs in order to loosen up old pleuritic adhesions. Where there is not a bath-room the patient may sit in the middle of an English bathtub astride a chair, and the douche be applied from a pitcher. Doctors should prevent the marriage of tuberculous patients, and in married people, where the disease is progressive, should give directions for the prevention of conception. Pregnancy sometimes gives rise to an illusory sense of wellbeing, but only to cause a more rapid decline after labor is over.

In discussion, DR. WICKES WASHBURN said that the ideal plan would be not a sanatorium where patients alone could go, but a farm colony to which the family could transport itself. Many of the objections to a sanatorium, its lonesomeness, its lack of occupation for the mind and the hand, and the difficultyof nostalgia would be removed by this plan. He presented the following resolution: "It is the sense of the New York State Medical Association that sanatoria should be established by the State of New York for the treatment of tuberculous patients; and this plan of treatment should include a farm colony where families of tuberculous patients might live."

DR. C. C. FREDERICK of Erie County then read a paper, entitled

REOPENING THE ABDOMEN FOR POST-OPERATIVE SEPTIC PERITONITIS, WITH REPORT OF CASES.

For general septic peritonitis after operation, the reopening of the abdomen is practically of no avail. All surgeons are agreed that patients' lives cannot be saved under such circumstances. For secondary septic peritonitis, however, due to defective drainage for instance, or to inoculation by the giving way of a set of sutures in a hollow viscus, prognosis is not so unfavorable. He had four such cases to report. Two of the operations were performed in the old days when we allowed a glass drainage-tube to remain in all cases of abdominal operations. Both of the infections took place because of the drainage-tube and both patients recovered after the insertion of a gauze drain which was brought out at the lower angle of the wound. In two recent cases the abdomen was reopened successfully for secondary infection caused by the giving way of sutures. In one an extra-uterine pregnancy was removed, the sac of which was so adherent to the intestine that a portion of the gut had to be resected. The Murphy button was used for this, and when symptoms of peritonitis developed it was thought that the button had given way. The button, however, was found perfectly in place, but a portion of the gestation-sac had given way. The general peritoneal cavity seemed to be infected, and there were spots of lymph here and there on the intestines. The case looked hopeless, but after flushing out the abdomen the wound was closed once more. The patient left the table pulseless and remained so for twenty-four hours. When the speaker left the hospital he signed a blank death-certificate feeling sure that she would

die. At the end of thirty-six hours the pulse returned and the patient lives to show the death-certificate as a memento.

In another case a purulent salpingitis had opened through the rectum and through the bladder. At operation the bladder had to be resected. Symptoms of peritonitis set in, and when the wound was opened the sutures in the bladder were found to have given way. The abdominal cavity was flushed out and the symptoms gradually ameliorated. Fluctuations of temperature, with sweating and excessive prostration continued. In this state of general sepsis the patient died. After death no peritonitis was found, and it was the septic condition that caused death.

A paper was then read by DR. CROTHERS of Hartford, Conn., entitled

MORPHINISM AMONG PHYSICIANS.

Dr. Crothers who, as a statistician, has collected the statistics of the morphin, cocain, and whisky habits for the last nine years, has had his attention called to the number of physicians who give way to these habits. In a series including some three thousand physicians in the Eastern and Middle States he found that 21 per cent. indulged in alcohol to excess, that 6 per cent. had the opium habit, and that 10 per cent. indulged in opium and other drugs. A well-known professor of materia medica had the morphin habit; eight of his students developed the same thing. Physicians often switch off from alcohol to opium or other drug habits. These drug habits induce a form of chronic invalidism. While under the influence of the drug they are apt to be of a serene temperament, but are irritable and excited when out of it. They have a distinctly lower moral sense and develop tendencies to suicide, or to backbiting, or to kleptomania. They are liable to adopt peculiar notions, and to write rambling papers for medical societies. It is to be remembered that suggestion plays a very important rôle in the cure of these diseases. It is much more important than any drug, or than any form of treatment that the patient should be convinced that he is surely going to get rid of the habit and that without much difficulty.

The next paper was read by DR. CHARLES ALLING TUTTLE of New Haven, Conn. Its title was

ALBUMINURIA: ITS PROGNOSTIC VALUE IN CHRONIC NEPHRITIS.

Albuminuria does not necessarily mean the presence of nephritis, nor does its absence signify that the kidneys are healthy. Casts may be present in the urine without there being Bright's disease and not every sample of urine from a patient suffering from Bright's disease will contain casts. Casts and albumin may occur while the patient is in perfect health. The advance of chronic nephritis may be most insidious. Our present methods of examining the urine by no means give us the assurance that we have been taught to suppose. All the clinical symptoms of a case should be carefully watched and no exclusive diagnosis made on the strength of one or two negative examinations of the urine.

The next paper, read by DR. WILLIAM P. SPRATLING, Superintendent of the Craig Colony for Epileptics at Sonyea, New York, was entitled

CURABILITY OF EPILEPSY AND HOW IT MAY BE ACCOMPLISHED.

Early treatment of epilepsy is the important thing. For this purpose it must be recognized early. The ordinary text-book definition of epilepsy is often misleading. We are led to expect tonic and clonic convulsions and loss of consciousness. As a matter of fact in true epilepsy there may be either tonic or clonic convulsions, not necessarily both, and there need not be loss of consciousness. Nocturnal fits may continue for a long time unrecognized; even diurnal fits of true epilepsy may be set down as mere fainting spells. If such mistakes are made it will be impossible to prevent the formation of the epileptic habit in the nervous tissues.

It is to be borne in mind that most convulsions are the result of some pathological lesion of the central nervous system. The speaker remembered once asking Dr. Jacobi his opinion of convulsions that occur as the result of dentition. He said it was not improbable that they were due to slight hemorrhages in the brain. Some years afterward he saw with Professor Virchow specimens which demonstrated this condition, and not long afterward, discussing the subject with Dr. Heughlings Jackson, agreed that such slight hemorrhages probably occurred. A number of patients that come to Craig Colony for treatment seem to have had epileptic convulsions in infancy, some during the first six months. A number of cases develop between the ages of ten and sixteen, that is, at the time of puberty.

The important etiological element in all epilepsy is the predisposition. Thirty-five per cent. of all the patients at Sonyea were born of epileptic parents. Sixty-six per cent. come from neuropathic families, or families in which there is some diathesis such as syphilis, gout, diabetes, etc. Do not give drugs to suppress the fits; they impair digestion and disturb assimilation. The giving of bromids that is so common now is always harmful in the end. It suppresses the fits, but does nothing to cure them. Operations have practically never done any good. In forty-four operations of which he has the records only one patient was improved and even that is doubtful. Nine of the patients at Craig Colony were operated upon before they went there. They were benefited for awhile, but the convulsions returned as before. One of these patients had been to Von Bergmann in Berlin and to Horsley in London and both of them had refused to operate. A New York surgeon was found, however, willing to perform an operation. Needless to say no good resulted. The important thing for epileptics is the regulation of their diet and exercise. They should not be allowed alcohol and very little tea or coffee. The regulation of their diet should be carefully done, for they are apt to gormandize. At the colony they are always prescribed a complete change of life. Those accustomed to indoor life are gradually accustomed to work in the open air. The weak and delicate patients are given a modified rest cure. So far eight per cent. of the patient have been discharged as cured.

(To be Continued.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, NOVEMBER 11, 1899. NO. 20.

ORIGINAL ARTICLES.

THE ADVANCE IN OUR KNOWLEDGE OF TYPHOID FEVER.[1]

BY HERMAN M. BIGGS, M.D.,
OF NEW YORK;
PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE, AND ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

No apology is needed in introducing a discussion on typhoid fever, for although no medical subject has been more written about, excepting possibly tuberculosis, yet for many reasons this must always remain of absorbing interest; and the advance in our knowledge of this disease in its various phases in recent years and the terrible devastation created by it among our troops during the war with Spain have created a renewed interest in it.

The history of the development of our knowledge of typhoid fever forms an exceedingly interesting and instructive chapter in the history of medical progress. The fevers, so-called, in former times alone caused a much greater mortality than the total mortality from all causes now occurring in favorably situated localities. Under the head of fevers in the death returns were included typhoid, typhus, and malarial fever, and probably many other forms of disease whose nature was unrecognized. The differentiation was not then possible, although the occurrence of continued fever with intestinal ulceration was well known, and the characteristic types of malarial fever were long ago clearly recognized.

The first great step in the advance was made through the observations and writings of Shattuck, Gerhardt, Bartlett, and Flint in this country, and Sir William Jenner in England, which defined the characteristic anatomical lesions of typhoid fever and made possible its clinical differentiation from typhus. The first period in the history of our knowledge of the disease may be said to have terminated then at about 1850. The second period may be said to extend from this time to 1880, when the discovery of the typhoid bacillus by Eberth was announced, although for a number of years after this Eberth's observations had but little influence. During this second period important contributions were made to the morbid anatomy, clinical history, diagnosis, and treatment of this disease. The third period extends from 1880 to the present time, and it is during this time that the greatest advances have been made.

Until accurate bacteriologic investigations had corrected and extended our knowledge, enteric fever seemed a better name for this disease than typhoid fever, as it indicated the site of what appeared to be the essential anatomical lesions of the disease. The involvement of the solitary follicles and patches of Peyer in the ilium and the presence of ulceration in them were essential post-mortem for a diagnosis. Although many observers held the opinion that a typhoid infection might exist without the presence of ulceration, or, indeed, of any changes in these structures, yet the proof was wanting. Now, however, there is abundant evidence to show that while the primary localization of the typhoid infection in the lymphatic structures of the small intestines is the usual one, and is present in a very large proportion of all cases, yet the primary infection may be centered in other organs or tissues of the body, or it may take the form of a typhoid bacillus septicemia. Thus carefully observed cases have been described in which the identity of the typhoid bacillus has been established, in which the primary site of the infection was situated in the respiratory tract, the urinary tract, and the mesenteric glands and the spleen, and a number of cases have been reported in which the intestinal ulceration was confined to the colon. Many cases also of cholangitis, cholicystitis, meningitis, pyelitis, laryngitis, and inflammations of other mucous membranes have been reported as having resulted from the action of the typhoid bacillus. In the large majority of these latter the lesions have occurred secondarily and as complications of typhoid lesions of the small intestine. Of course in this connection those cases are not referred to in which various complications have occurred in the course of this disease, which were due to other micro-organisms, such as the streptococcus, staphylococcus, colon bacillus, etc. It is evident, therefore, that we can no longer properly speak of typhoid fever as enteric fever, unless under this latter term are classed only those cases in which the infection is localized primarily in the intestines.

It seems probable, from our present knowledge, that generally at some time in the course of typhoid fever the bacilli are present in the circulation in

[1] Introducing a Discussion on Typhoid Fever before the New York Medical Association at the Sixteenth Annual Meeting, held September 23–26, 1899.

small number. Only occasionally, however, do they produce local inflammations outside of the abdominal lymphatic system. Their entrance in the majority of instances, but not invariably, is no doubt through the lymphatic structures of the intestines. That the typhoid bacilli do make their way into the general circulation at some time in the course of typhoid fever in the majority of cases is shown by the presence of the bacilli in the rose-colored spots of the typhoid eruption; in the urine during the later course of the fever, and sometimes for long periods after the beginning of convalescence; and finally by the possibility of the demonstration of these organisms in the blood in many cases by proper methods of examination. Still further evidence is afforded by the presence of the bacilli after death in various organs and tissues of the body, aside from those of the abdominal lymphatic system, an observation which can only be interpreted as giving testimony to their presence in their circulation at some time during the course of the disease. Several years ago Koch told the writer that it was a common practice in the Institute for Infectious Diseases in Berlin to make cultures from the rose spots by snipping out portions of the skin for the positive diagnosis of this disease. We do not know why in rare instances the typhoid bacilli produce lesions in various parts of the body and in others do not—although present in the circulation—but this difference is probably due in part to something which causes a local diminution in resistance, and in part also, perhaps, to differences in the dose and virulence of the virus in different cases. As is now well known, any kind of injury to the tissues of the body render them more susceptible to various infections.

In no phase of our knowledge of typhoid fever have greater advances been made than in the means for accuracy of diagnosis. The observations of Pfeiffer and Gruber, showing that the blood serum of persons ill with typhoid fever exercises a peculiar agglutinating influence on the typhoid organisms in recent cultures, was reduced by Widal to a form in which it was practically available for diagnosis. This test has proved of inestimable value in affording confirmatory evidence, not only in the routine diagnosis, but especially as furnishing most valuable information in the differentiation and identification of obscure cases. While a negative result from the Widal test cannot be regarded as having much significance, a positive reaction in proper dilution is to be regarded as almost conclusive proof of the recent or earlier existence of typhoid fever in the subject. If the reaction develops while the patient is under observation—being absent in earlier and present in later tests—it is, in my opinion, to be considered as almost as strong a proof of the existence of typhoid fever as the demonstration of the bacilli themselves. Thus while the Widal reaction may be very late in its appearance, may sometimes appear only during a relapse, or may be entirely absent in undoubted, and even in fatal cases of the disease, yet when present is of the greatest possible value. The test when present in a dilution of 1 in 50 is to be ranked in importance, in the value of the positive information which it gives, next to that afforded by the demonstration in various diseases of the presence of the specific organisms causing them, as the tubercle bacillus in tuberculosis, the diphtheria bacillus in diphtheria, and the cholera bacillus in Asiatic cholera.

Still more valuable information may be derived, but at much greater expenditure of time and skill, by the demonstration, which is possible in many cases of the typhoid bacilli in the feces, urine, rose-spots, or blood of typhoid-fever patients. The newer methods of differentiation of the typhoid bacillus from the members of the colon group devised by Elsner, Hiss and others have made such demonstrations practicable in many cases where good laboratory facilities are at command. These methods, however, must be much further simplified and rendered more exact before they can be regularly employed as routine measures.

Renewed attention has been devoted in the last two or three years to the value of the diazo-reaction of Ehrlich in the diagnosis of this disease. Nearly all observers are agreed as to its almost constant presence in a decided form in the early stages. Krienkiewicz, as the result of over 16,000 tests, reports that it is always present in the first and second stages of typhoid fever. Michaelis, from Von Leyden's clinic, states that it is almost invariably present early, and sometimes as late as the twenty-second day. He regards it of great value in the diagnosis of early and doubtful cases. Thus it may be present between the third and seventh day, before the Widal reaction occurs, before the eruption appears, before there is any considerable enlargement of the spleen, and when constipation exists. In such cases a decided diazo-reaction may be of much value in confirming the diagnosis.

It is also very frequently present, unfortunately for its diagnostic value, in general miliary tuberculosis—an affection which is frequently mistaken for typhoid fever. The reaction may be of great service in the early diagnosis of relapses of typhoid fever, as it is usually present in the first days of the relapse. The increase or decrease in the intensity of the reaction has much prognostic value, and its gradual

disappearance in a case indicates an abating of the infectious process and of the fever. In my own experience it has been present in a very large proportion of the cases of typhoid fever occurring in my service during the last two years at Bellevue Hospital and St. Vincent's Hospital.

Important observations have been made in recent years with reference to the relation of typhoid fever to disease of the biliary passages and the gall-bladder. The frequent infection of the gall-bladder by the typhoid bacillus in typhoid fever has been well established, this infection apparently taking place, not through a direct extension from the intestinal canal, but through the portal circulation. Probably in many instances the presence of the typhoid bacilli in the gall bladder and biliary passages is not followed by any changes in these parts, but sometimes apparently cholicystitis and cholangitis result, or infection in the gall-bladder may serve as the starting point for the development of gall stones. The long persistence of the bacilli in the gall-bladder in some cases is a remarkable feature of these infections, the bacilli having been found in a few instances many years after the attack of typhoid fever.

The results of preventive inoculations against typhoid fever, although still very incomplete and inconclusive, seem to afford good ground for hoping that they may be of the greatest service in the prevention of this disease among troops, and among those who for any reason are much exposed to possible infection because of the nature of the sanitary surroundings or their occupation. Wright, of the Army Medical School at Netley, has been for a number of months in India inoculating English troops who volunteer to receive treatment It is stated by him that of 200 attendants at the Maidstone Asylum 95 were inoculated, and none contracted the fever during the epidemic there, while of 105 who refused to undergo the process 19 sufferered from the disease. At Khartoum, of 8 young subalterns 6 consented to receive the inoculations; the other 2 declined, and of these 1 was ill with enteric fever and the other died, while all of the 6 inoculated officers escaped. Wright states that he has inoculated 3000 soldiers, and it is reported that many of the troops going to South Africa are being subjected to this treatment.

Preventive inoculations have also been advocated by Pfeiffer and Marx and by Haffkins. These are made with attenuated or sterilized cultures, and it has been shown experimentally that they produce immunity in animals. They are followed by a febrile reaction lasting for from one to three days and some local pain, swelling and tenderness at the site of the injection. The blood-serum of patients subjected to such inoculations acquires agglutinating properties on typhoid cultures similar to that following an attack of the disease. Very little is to be said as to the specific treatment of typhoid fever. All of the attempts thus far made in the production of a curative serum have been followed by unsatisfactory results, or at least the favorable results reported have not been confirmed by other observers.

The bacteriological investigations have not only greatly broadened our conceptions in respect to the nature and manifestations of typhoid fever, but they have also contributed in a most material way to our knowledge of prophylaxis. How unsatisfactory do the earlier methods of disinfection now seem when we know that the urine, which has usually received little or no attention, contains the typhoid bacillus at some period in the course of the disease, especially during convalescence, and that these bacilli may be present in almost incredible number—estimated by Gwyn in one instance as 500,000,000 in each c. c.—and that they may remain present in the urine for months and probably for years. In the observations made in the laboratories of the Department of Health, the examinations being made largely by Dr. Hiss, out of 51 cases of typhoid fever examined during convalescence, in the urine of 7, or about 14 per cent., typhoid bacilli were found, in some one instance in large numbers, repeatedly, and as late as the ninth week. They are rarely present, however, according to our observations, early; for in 80 cases examined for diagnosis, or for confirmation of diagnosis, chiefly within the first two weeks of the disease, in only two instances were the results positive, and one of these was a case of renal infection by typhoid bacilli and not presenting at all the clinical features of this disease.

The bacilli are undoubtedly sometimes much more numerous in the urine than in the feces; but their presence in the urine is not necessarily in any way associated with the existence of renal disease. Specimens of urine containing them may show no evidence of any abnormality in the kidney or any portion of the urinary tract. The urine may be perfectly clear and liquid and show nothing in any way abnormal excepting the presence of the bacilli, or in some instances it may be slightly cloudy. Cases have been reported, however, and especially cases of so called renal typhoid, in which the presence of bacilli in the urine has been associated with acute nephritis, and sometimes with pyelitis or cystitis. In some cases in which the organisms remain for long periods after an attack of typhoid fever it seems probable that the bacilli simply multiply in the

bladder without producing any change in the composition of the urine or in the mucous membrane of the bladder. It is evident that the danger of dissemination of infection through this, until recently unrecognized, medium may be very great. With this new fact before us, how easily can all the difficulties in the way of explaining isolated cases and peculiar outbreaks of typhoid fever be disposed of, and how perplexing and complicated become the preventive measures necessary.

One fact is much emphasized in the recent observations in this as it has been in many other infectious diseases, namely, the long persistence in some cases of the infectious element. We have only to mention the cases of diphtheria in which virulent organisms persist in the throat for months after complete convalescence; arrested cases of tuberculosis in which occasionally, without any evidence of any extension of the disease, or with apparently retrogressive changes, the cough may continue and the sputum contain tubercle bacilli for twelve or fifteen years or more; influenza with the persistence of the influenza bacilli and their agency in complicating affections occurring months after the initial attack, and probably the recurrence of relapses thus brought about; the presence of gonococci in gleet discharges or in the clumps of mucus from the deep urethra several years after the acute attack and their agency in the production of late complications; the persistence of the scarlatinal infection in the discharges from the catarrhal inflammations or suppurating glands left over after the complications of scarlet fever; the persistence of pneumococci in the saliva for long periods after recovery from pneumonia, and the recurring relapses of malarial fever. I say we need only mention these familiar facts to gain a renewed appreciation of the importance in the matter of prevention of the persisting organisms in the infectious diseases and their influence in the dissemination of disease. The newer observations in typhoid fever add to the accumulating mass of evidence of this nature.

The improvements in the methods of treatment of typhoid fever are best shown by the reduction in the case fatality from this disease. Large collections of statistics of cases treated between 1850 and 1880 before the general use of hydrotherapy show that the hospital death-rate varied from 18 to 36 or 37 per cent., the last excessive mortality being found under specially unfavorable conditions, as in military hospitals. Previous to 1885 the average mortality in the French army is said to have been about 37 per cent. In contrast to this it is reported by Brandt that in the Second German Army Corps, where hydrotherapeutic measures have been thoroughly and systematically carried out, the mortality is less that 4 per cent. While cold baths have been systematically employed to a large extent in Germany since 1865, they were not in general use in other countries until a much later period. All recent reports show that through their systematic use the case fatality has been reduced in large collections of cases in various parts of the world to between 4 and 9 or 10 per cent., with an average of about 7 per cent. Where the mortality has been higher, 9 and 10 per cent., investigation has usually shown that a considerable proportion of the cases have not come under observation until the second or third week of the disease.

But while there can be no question that the use of cold baths has contributed more to this result than any other measure, yet I cannot but believe that improvements in the treatment in other respects have contributed, to no small extent, to this result. We have learned to use drugs less and less and to watch carefully the nutrition of the patient. I believe all physicians who see many cases in consultation in private practice are impressed with the tendency of the general practitioner to do too much; too often the treatment is positively injurious. Hospital patients generally receive few drugs. The average death-rate from typhoid fever in the large hospitals of the world is certainly not more than one-half, and probably not more than one-third what it was between 1850 and 1865 or 1870. The possible saving of life afforded by surgical interference in the cases of perforation of the intestine needs only passing mention in this connection.

The problems presented to sanitary authorities by the more recent observations in the bacteriology of some of the infectious diseases are simply insoluble from a practical standpoint. Who has proposed any practicable method for dealing with those cases of diphtheria in which the bacilli, persisting in the throat for months after complete convalescence, retain all their virulence and remain unaffected by any local measures of treatment? It is also evident in view of our present knowledge that the urine of every case of typhoid fever should be, not only systematically disinfected, but that it should be examined at intervals during convalescence, and the case should be kept under observation until it is permanently free from bacilli. That such measures can at present be actually carried into effect is manifestly impossible.

Fortunately in this disease it seems probable from the limited observations thus far made that the methods suggested by Richardson, of irrita tion of the bladder with 1 in 50,000 solution of corrosive sublimate and the internal administration

of urotropin cause the disappearance of the bacilli from the urine within a short time.

The frightful possibilities yet involved in the prevalence of typhoid fever were presented in a most lurid light during the Spanish war. In the face of all of the modern progress in the knowledge of the infectious diseases and the means for their prevention, and in spite of the extraordinary advances in sanitary medicine in all its phases, hundreds and thousands of our soldiers sickened and died of this disease; and many returning home while ill or during convalescence carried with them and spread broadcast typhoid infection in many towns, villages, and rural districts throughout the United States. Other hundreds and thousands of people have since contracted the disease as the result of the dissemination of the infection.

Typhoid fever, which previously prevailed particularly in the cities and large towns, is becoming more and more a disease of rural districts. In the larger cities, which are provided with a pure water-supply and an efficient sewerage system, the disease has become to a large extent one of those which results from importation of the infection from outside. The morbidity and mortality rates from typhoid fever in New York City, for example, are comparatively low (death rate .15 per 10,000 population in 1897 and .18 in 1898; increase due to typhoid fever among soldiers), and of the cases which occur careful investigation has shown that a large proportion have contracted the disease outside of the city. Of those cases developing within the city limits a few are undoubtedly the result of the transmission through direct contact; others result from milk infection derived from the country districts—several such groups of cases are traced out each year—still others are undoubtedly the result of infection through the contamination of food, oysters, fresh vegetables, etc.; a few probably receive their infection while bathing in the water of the North or East River contaminated by the city's sewage; in still others the source of the infection cannot be found, but from the very limited number of these cases it is quite evident that they are unrelated to the water-supply.

The cases resulting from contact are undoubtedly due to infection through lack of sufficient care in regard to cleanliness, the evidence of transmission through the air being far from conclusive. In these contact cases the infection is probably caused by the soiling of the hands, or the introduction of the infectious matter through the food, drink, or in some other way into the mouth. I believe there are few cases occurring in New York City which do not result from infection by some one of the means described, and for the most part derived from without the city limits. If a city is content to use for drinking purposes a water into which its own sewage or that of its neighbors is discharged, as is the case in a number of cities in this and other States, the prevalence of typhoid fever cannot be considered remarkable. The permanent and considerable prevalence of this disease in any city, in view of our present knowledge, stamps the authorities as ignorant, corrupt, or grossly indifferent to the welfare of the inhabitants. All of the advances have emphasized more and more strongly the importance of proper sanitary conditions in its prevention.

I have only attempted to indicate most briefly some of the more important contributions to our knowledge of this disease and desire to add just a word in conclusion as to the problem of prevention in the future. The solution of the problem lies in the sanitary education of our medical men and of the people. I long ago insisted upon the importance of this, and Osler has strongly emphasized this phase of the question in a recent admirable address before the New York State Medical Society.[1] Hygiene is a subject which is not studied and not taught in this country. Its simplest elements are known to the very few, even of the medical profession There is scarcely a medical school in which the students have a single course of lectures on general hygiene which is worthy of consideration. In most of them the subject is not taught at all, excepting incidentally in connection with bacteriology and medicine. The natural result is that the medical profession as a class are very deficient in a proper knowledge of the subject, or any appreciation of its importance. Sanitary officers, generally medical men appointed through political influence, without reference to fitness, receive little or no compensation for their services, and in the smaller towns, villages and rural districts are unfamiliar with sanitary methods; wanting in special knowledge of sanitary subjects, and ignorant of the possible results of sanitary reform. They have neither the means, nor can they afford the time, to acquire the knowledge requisite for the meager compensation received. The laity, knowing still less than the medical profession, are content with the existence of bad sanitary surroundings so long as they do not offend the sense of sight or smell. Consequently, we in the United States, who in almost all other practical matters and in those concerning the comforts and luxuries of living, are far in advance of European countries, in this matter which concerns our health and lives are fully a generation behind.

[1] Medical News, February 25, 1899.

An improvement in the existing conditions is to be brought about I believe:

First, by teaching hygiene in our public schools, our medical schools, and our universities.

Second, the establishment of schools for advanced work in preventive medicine.

Third, the education of men to fill the positions of medical officers of health, and the provision for them of adequate compensation and security of tenure in office.

When these measures have been instituted, and the medical profession and the laity have been gradually educated to the necessity of the maintenance of proper sanitary conditions and what these mean—the purity of the water-supply, good sewage, clean streets, and clean soil in our towns and cities—then, and not till then, will the great advance in our knowledge of typhoid fever show its full effects in the reduction of morbidity and mortality; then, and not till then, typhoid fever will begin to disappear, and the last and most important advance—the prevention of disease—will be recorded by a rapidly decreasing morbidity and mortality list, and the occurrence of such a dreadful tragedy as is recorded in the sanitary history of our war with Spain will be impossible.

EYE COMPLICATIONS IN TYPHOID FEVER.[1]

By ALVIN A. HUBBELL, M.D.,
of Buffalo, N. Y.

Eye diseases complicating typhoid fever are of such rare occurrence that many practitioners of large experience have never met them. Partly on account of their great infrequency, but more particularly because they so closely resemble in their symptoms, diagnosis, course, and treatment the same diseases arising under other circumstances, a brief and summary consideration of them is sufficient.

It is probable that some of the complications involving the interior of the eye are overlooked through neglecting to use the ophthalmoscope; but even in that case their frequency is not as great as would be expected if we take into consideration the undoubted quantity of toxins generated during the typhoid-fever process and taken up into the circulation, and the diffusibility of the typhoid-fever germs, throughout the body and their occasional pyogenic character as set forth in that classic on the "Surgical Complications and Sequels of Typhoid Fever," by our distinguished guest and learned colleague, Professor Keen.

Conjunctivitis, both catarrhal and herpetic, and inflammations and ulcerations of the cornea are seen more frequently than other eye complications, unless, perhaps, we except those more strictly functional troubles, manifested by dilatation of the pupils and weakness of accommodation. Retinal hemorrhages seem to be next in frequency, according to published reports. Other diseases which have been observed are hypopyon, suppurations of the deeper structures of the eye and panophthalmitis, iritis, cyclitis, choroiditis, opacities of the vitreous humor, opacity of the crystalline lens, optic neuritis, both retrobulbar and intra-ocular, with subsequent partial or complete optic-nerve atrophy, neuroretinitis, embolism of the central retinal artery, orbital cellulitis, thrombosis of the orbital blood-vessels, orbital hemorrhage, paralysis of the extra- and intra-ocular muscles, together with scotomata and general impairment of vision, which are but secondary to the inflammations, atrophies, or hemorrhages present, or perhaps to an overpowering toxemia which but temporarily disturbs vision and muscular action. Hemianopsia has been recorded, but can only be due to some lesion posterior to the optic commissure and not to any disease of the eye itself.

These complications seldom develop until the later stages of typhoid fever. Some of them are post-febrile in their manifestations, particularly the ocular palsies and optic-nerve atrophy.

As early as 1817 Carron du Villards[1], in an epidemic that was undoubtedly typhoid fever, observed a series of cases of persistent amaurosis. Numerous cases of the various complications above mentioned have since been recorded from time to time, the historical details and bibliography of which may be found in the exhaustive works of Fœrster,[2] Max Kneis,[3] Emile Berger,[4] and in the excellent chapter by George E. de Schweinitz in the monograph of Professor Keen already mentioned. Charles Stedman Bull has also given a brief résumé of the subject in a paper published in the *Medical Record*, April 24, 1897.

While typhoid-fever germs may, at times, be the active agents in the production of eye diseases, it is probable that their toxins, judging by analogies to diphtheria and other infectious diseases, play the more important rôle.

But whether the germs or toxins are chiely causative, they are potent in proportion to their virulence, to their detention by an enfeebled circula-

[4] "Les maladies des yeux dans leurs rapports avec la pathologie générale," Émile Berger, Paris, 1892.

tion, and to the diminution of tissue resistance. In many cases their action may fall short of producing inflammation, amounting only to functional disturbance of vision and ocular motility, as shown by temporary impairment of vision, vascular congestion, diminished winking reflex, weakened accommodation, and dilated pupils. Such cases, as might be expected, are by far the most frequent. In other cases a superabundance of germs or an unusual virulence of the toxins in the blood often induce in the eye tissues, at a low ebb of vitality, active inflammations that terminate in destructive suppuration and ulceration The uveal tract, by reason of its great vascularity, and the cornea because of exposures, are peculiarly open to such attacks; hence, the iritis and chroiditis. The delicate nerve elements of the eye are also susceptible to such invasions; hence the neuritis and retinitis.

Besides these conditions which are evidently due to local germ action or intoxication, there are some affections which are transmitted by contiguity from preexisting, complicating diseases of the adjoining sinuses. This undoubtedly accounts for certain cases of conjunctivitis and orbital cellulitis. Embolism of the central retinal artery, with the immediate blindness which takes place in the eye whose retina is thus deprived of its blood-supply, thorombosis of the orbital veins, hemorrhages into the orbit, or intra-ocular hemorrhages are all secondary to preceding, complicating affections of the endocardium, blood-vessel walls or the blood.

In low states of typhoid fever when the toxemia is so profound as to almost paralyze the winking reflex and the secretory function of the glands that moisten the eye, the conjunctiva and cornea become desiccated, their delicate epithelium breaks down, and microbic invasion takes place with all the attendant evils of xerosis, ulceration, abscess, and ofttimes total destruction of the eye.

Fewer cases of intra ocular complications would pass undiagnosed, if practitioners would examine the eyes of typhoid-fever patients with the ophthalmoscope.

The prognosis of these complicating diseases is made more unfavorable in typhoid fever than when they are found in persons of otherwise fairly good health, and the results are bad, especially in the ulcerative and suppurative affections, in proportion to the gravity of the primary disease.

The same treatment should be adopted that would under other circumstances be suggested. Corneal and conjunctival affections may often be prevented by attending to the closure of the eyelids, if they are inclined to remain open, and to keep the parts moist by occasionally instilling into the conjunctival sac a drop or two of a normal saline, or very mild antiseptic solution.

ANGIOTRIPSY.[1]

By CLEMENT CLEVELAND, M.D.,
of New York.

Torsion and compression of the arteries are really the same in effect, and are both old. They both produce barriers against the escape of blood by causing adhesion of the inner surfaces of blood-vessels and the formation of clots. It is a well-known principle in surgery that whatever favors the production and retention of a blood-clot in a wounded vessel favors the arrest of hemorrhage. Torsion and compression of small arteries have been employed for years, and are effectually employed in every surgical operation to day.

Thirty years ago, to extend the principle to the control of hemorrhage from large vessels, Dr. J. C. Nott of New York City—in those days a man well-known as a surgeon in gynecology—invented what he named a "rectilinear écraseur." It was designed for the cure of hemorrhoids, the amputation of the cervix uteri, removal of portions of the walls of the vagina in cystocele, rectocele, and procidentia, and, to quote his words from an article published at the the time, October 10, 1871, in the *Atlanta Medical and Surgical Journal:* "This instrument answers well in the operation of ovariotomy, to sever adhesions between the tumor and walls of the abdomen, and, I think, might be trusted to divide the pedicle of an ovarian tumor, but here it has not been tested." The instrument was used extensively at the time for the cure of hemorrhoids, and a description of it, with report of cases, appeared in the *Medical Record.* It was at least an attempt to apply to large vessels the means employed in controlling hemorrhage from small ones. His instrument may rightly, then, be said to be the forerunner of the powerful instruments for blood control which are now beginning to be successfully and extensively used. A drawing of Dr. Nott's instrument may be seen in Tiemann's catalogue of surgical instruments.

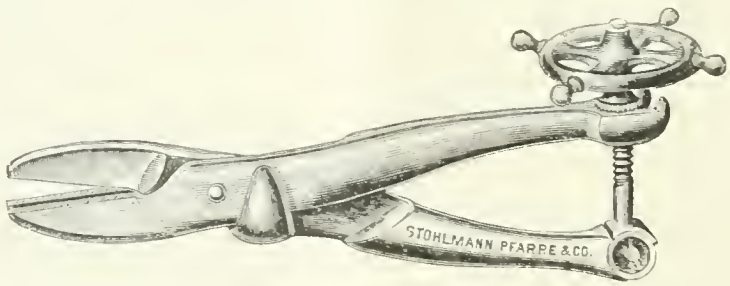
In 1897, Doyen of Paris devised an instrument for controlling hemorrhage which he called a "vasotribe," and reported a number of successful cases with its use. Later, Thumin of Berlin, after seeing and using the Doyen instrument, improved upon it in gaining greater pressure.

In 1898, Tuffier of Paris brought out his instrument, which he named an angiotribe, or vessel crusher. With it he claims to produce a pressure

[1] Presented at the Twenty-fourth Annual Meeting of the American Gynecological Society, held at Philadelphia, May 24, 25, and 26, 1899.

of three thousand pounds. I do not consider the name happily chosen, because the tissue, examined by the microscope after the use of the instrument, shows that it is not a crushing that is produced, but compression.

In the early part of December, 1898, Dr. Appert of Paris, who was sojourning in this country for the purpose of study, and who had been a frequent attendant at my clinic at the Woman's Hospital, spoke to me of this instrument of Tuffier and recounted the successes that had been obtained with it. He told me, moreover, that it had met with a great deal of defiant opposition, but was slowly and steadily forcing its way onward, because of the satisfactory and indisputable successes that were being constantly reported from its use. He promised to obtain an instrument for my use. On January 9th of this year Dr. Appert made good his promise and brought me the angiotribe, which he had just received from Paris. I at once put it to the test, and I understand, it was the first use made of it in this country. You will see, by examining the instrument or the drawing of it which is here presented, that it is merely a powerful clamp made to stand an immense leverage. The blades on their clamping surfaces present in the center of each a longitudinal groove; this is for a distinct purpose, which will appear. The pressure is produced by means of a screw, upon which works a wheel or a windlass. When in use one end of the screw is locked upon the end of one arm, while the other end fits into an open cut or claw in the end of the other arm.



In hysterectomy the instrument is applied just as any clamp would be, and the great pressure is attained by means of the wheel or windlass, by turning which the arms or handles are forced closer and closer together, and by that means, of course, bring the blades more and more firmly in coaptation. It is the rule to keep up the pressure during two minutes, that being found a sufficient time for the formation of clots in the vessels. When the uterus is cut away a short stump is designedly left, projecting beyond the surfaces of the blades. When the instrument is removed a flat ribbon of tissue, the width of the blades, is seen, with a ridge of tissue on the upper and under surfaces corresponding to the horizontal grooves above mentioned. The design is that, after the removal of the angiotribe, there will be five barriers against the escape of blood. By this is meant that blood-clots will be formed in the vessels on both sides of the blades and also in the small, central spaces produced, or rather left, by the grooves, and the compressed surfaces will be thoroughly agglutinated. These barriers are all essential, and especially the one on the inner or uterine sides of the blades, where a stump of tissue should always, as I have said before, be left to retain the clots at this point.

I had been using for a year and a half Dr. Skene's electric clamp, and had found such continued satisfaction from its use that I had become an ardent advocate of it, and, in fact, had begun to feel that there was nothing further or better to be wished for. The emancipation from the use of ligatures had afforded me the keenest satisfaction.

My first success with the angiotribe was so thoroughly startling and so satisfactory that I had to at once completely reverse my decision and admit that this new method was really a step in advance of the electric clamp. I saw that the electric clamp would still have its uses, but that the angiotribe must succeed it in the vast majority of vaginal and intrapelvic cases. I at once reported my first case in a short paper at a meeting of the Practitioners' Society of New York, held January 13, 1899. This paper was published later in the New York *Medical Record*. I quote here what was said regarding the method of application of the instrument:

"I had at my clinic that afternoon a case of double tubo-ovarian abscess, with a large, septic uterus. The vagina was capacious, so it was a favorable case for the exhibition of the instrument. The method of operation was as follows: The anterior incision across the cervix was made by the electric knife. The bladder was then separated from the cervix up to the vesico-uterine fold of the peritoneum. The posterior incision was made by the electric knife, and the tissues were thoroughly separated by the finger into Douglas' pouch. The incision was made

complete around the cervix by severing the vagina at the sides of the cervix with the electric knife. The cervix was then grasped at either side of the external os by two traction forceps, and divided longitudinally up to the junction of the cervix with the body. The left half of the cervix was drawn down and to the right, while the angiotribe was applied to the lower section of the left broad ligament. The pressure of the forceps was applied to its utmost capacity of three thousand pounds for the period of two minutes. The left portion of the cervix was then cut away from the forceps and the instrument removed. Not the slightest bleeding followed, showing that the vessels had been so completely crushed that their inner walls were thoroughly glued together. The same was done upon the right side. No bleeding followed. I then opened into the abdominal cavity anteriorly and proceeded with the bisection of the uterus until it was completed. I found, upon passing my finger into the pelvic cavity, an abscess of the tube and ovary of the left side. With some difficulty these were dug out from their bed of adhesions and drawn out. The angiotribe was then applied to the upper section of the broad ligament of the left side, back of the diseased tube and ovary, for the same period of two minutes, then the left half of the uterus was cut away and the instrument removed, and no blood followed. The same process was repeated on the other side, with a similar result. The pelvic cavity and vagina were packed with gauze in the usual way and the patient was put to bed

In this case, as following the use of the electric clamps in vaginal hysterectomy, there was the minimum amount of pain and not the slightest hemorrhage. The patient is making an uneventful recovery, with scarcely an elevation of temperature above the normal.''

Feeling that this method was a most important innovation and that others would wish to have the opportunity of employing it, I at once set to work to have the instrument copied, and Stohlmann, Pfarre & Co. of New York succeeded, after several trials, in producing an instrument fully equal to the French original. In fact, I examined every one they made until this result was attained. It may seem an easy thing for a skilled artisan in this craft to turn out a satisfactory copy of an instrument if he only has the original in his hand. This, however, does not seem to be a trait of the instrument-maker of to-day. The first instrument produced was too weak in its handles, and the edges of the blades were sharp and cutting instead of being smooth and rounded, as also the edges of the grooves; and, moreover, when full pressure was applied the blades were warped upon each other for at least a sixteenth of an inch. These difficulties were remedied as soon as the defects were pointed out. The wading through these difficulties, however, took a great deal of time. The requirements are so thoroughly understood now that I think no one need hesitate to purchase an instrument of American manufacture. I would advise, however, most careful examination before doing so, to make sure that the above-named defects do not appear.

I was enabled to continue my work with the French instrument, as Dr. Appert allowed me to retain it while he was on a three-months' trip to Mexico and the South. On his return he loaned it to other surgeons in this city, and I believe all have reported favorably in regard to it. The first accurately made instrument from Stohlmann, Pfarre & Co. is in constant use at the Woman's Hospital.

Though I have no right to quote my confrères upon the staff of the hospital, yet I think I am right in saying that the general opinion among them is decidedly in favor of the method.

As a result of the work in my service with the angiotribe at the Woman's Hospital, I present here the histories of twenty-six successful cases. An epitome of each history is here given, merely for the sake of the diagnosis and the result.

Case I.—Mrs J., aged twenty-three years, admitted to the hospital in the latter week of December, 1898. Married two years; one child born fourteen months after marriage. Gives the history of peritonitis after confinement.

Symptoms.—Constant pain in both iliac regions. Three weeks ago had recurrent pelvic peritonitis. Examination revealed enlarged, fixed uterus, with masses on both sides.

Diagnosis.—Double pyosalpinx, with probable septic uterus

Operation, January 9, 1899. Vaginal hysterectomy, with double salpingo-oophorectomy. Angiotribe used. Third day after operation temperature reached $103\frac{1}{5}^{\circ}$ F., but subsided to 99° F. on the fourth day. Subsequent history unimportant. Recovery.

Case II.—Mrs. W., aged fifty-four years, entered the hospital early in January, 1899. Married twenty five years; one child, born twenty-one years ago. One miscarriage, eighteen years ago.

Symptoms.—Pain in the right ovarian region. Has been flowing somewhat profusely for two years, sometimes lasting two weeks at a time.

Diagnosis.—Carcinoma uteri.

Operation, January 16, 1899. Vaginal hysterectomy, with removal of adnexa by the angiotribe. Duration of operation, one hour. Convalescence uneventful. Recovery.

Case III.—Mrs. M., aged twenty-one years. Admitted to the hospital January 7, 1899. Married seven years; no children; four miscarriages, last one

in July, 1897. Menstruation irregular since July, 1897. No menstruation since October, 1898.

Symptoms.—Constant pain at present in left ovarian region and back.

Diagnosis.—Enlarged, adherent left ovary.

Operation, January 30, 1899. Posterior vaginal section for removal of left tube and ovary with the angiotribe. Duration of operation, forty-five minutes. Range of temperature after operation 98° to 99⅖° F. Uneventful recovery.

Case IV.—Mrs B., aged twenty-seven years, admitted to the hospital December 17, 1898. Married eight years; two children; two miscarriages, the last five months ago. Several weeks previous to entering the hospital was taken with sudden and violent pain in both sides of the abdomen. Last menstruation December 4th; flowed nine days.

Diagnosis.—Double pyosalpinx.

Operation, February 6, 1899. Celiotomy. Removal of intraligamentous ovarian cyst with angiotribe. Time of operation, forty-five minutes. Uneventful recovery.

Case V.—Mrs. V , aged forty-two years, entered the hospital January 13, 1899. Married fourteen years; no children; no miscarriages.

Symptoms.—Constant backache and pain in ovarian regions. No pain during menstruation, which is regular and lasts four days.

Diagnosis.—Fibroma uteri.

Operation, January 16, 1899. Abdominal hysterectomy, with removal of adnexa. Angiotribe used. There was a little oozing from one of the stumps, and it was thought wise to apply a catgut ligature. Patient recovered.

Case VI —Mrs. W., aged thirty years, entered the hospital January 23, 1899. Married eight years; no children; one miscarriage seven years ago Was then curetted, and has ever since been more or less irregular.

Symptoms.—Profuse leucorrhea; constant backache.

Diagnosis.—Retrodisplacement, with adhesions.

Operation, February 20, 1899. Celiotomy with the angiotribe. Both tubes and ovaries were found diseased. Double salpingo-oophorectomy. Duration of operation, one hour. Recovery.

Case VII.—Mrs. B., aged thirty-two years, admitted to the hospital March 1, 1899. Married six years: no children; no miscarriages. On February 2, 1899, began to flow, and was continuing to do so until she entered the hospital.

Symptoms.—A great deal of pain in the left iliac region

Diagnosis.—Ectopic gestation of the right side.

Operation, March 5, 1899. Celiotomy. Ruptured tubo ovarian pregnancy of the right side. Removal by the angiotribe. The appendix, which was found diseased and adherent to the right tube, was removed by the application of the electric clamp. Upon the removal of the electric clamp the stump was found gaping. This was immediately closed by catgut ligature and covered by serous membrane. Recovery uneventful.

Case VIII.—Mrs. H., aged fifty-four years, admitted to the hospital February 24, 1899. Widow; no children; menopause at fifty. In September last had a flow of blood that lasted ten days. Has had several floodings since.

Diagnosis.—Small fibroid in uterine wall.

Operation, March 26, 1899. Vaginal hysterectomy, with removal of adnexa. Angiotribe used. Time, one hour. Recovery.

Case IX.—Mrs. R., aged twenty-nine years, entered the hospital February 19, 1899. Married ten years; two children; youngest child seven years. Three miscarriages over seven years ago.

Symptoms.—Pain in the back and ovarian region since the birth of the first child. Menstruation somewhat irregular. February 4, 1899, flowed eight days profusely.

Diagnosis.—Tubo-ovarian disease of both sides.

Operation, March 6, 1899. Posterior vaginal section followed by the removal of the right ovary and tube with the angiotribe. Uneventful recovery.

Case X.—Miss P., aged forty-nine years, entered the hospital March 6, 1899.

Symptoms.—Has flowed almost constantly for three months, quite profusely.

Diagnosis.—Fibroma uteri.

Operation, March 9, 1899. Vaginal hysterectomy, with removal of adnexa. In this case the vagina was excessively small, and there was naturally some difficulty in applying the angiotribe. The perineum was ruptured during the process, and this was at once repaired. The patient was out of bed in three weeks. Complete recovery.

Case XI.—Mrs. B., aged nineteen years, entered the hospital March 11, 1899. Married four years; no children and no miscarriages. On December 30, 1898, the Alexander operation was performed. Complains of constant pain in the right ovarian region.

Diagnosis.—Diseased left ovary and tube.

Operation, March 13, 1899, by Dr. Broun, assistant surgeon. Posterior vaginal section, with removal of left ovary and tube. Angiotribe used. Recovery.

Case XII.—Mrs. B., aged forty-three years, admitted to the hospital March 9, 1899. Married twenty-five years; five children and thirteen miscarriages. Nine years ago had an abscess of the right ovary removed. July, 1898, menstruation became profuse. Since November flow has been continuous.

Diagnosis.—Cyst of left broad ligament. Fibroid or carcinoma of the uterus.

Operation, March 16, 1899. Celiotomy, followed by removal of the uterus and left ovarian cyst by Dr. Broun. Angiotribe used. Adhesions were numerous and dense. Duration of operation, three hours. Recovery

Case XIII.—Mrs. H., aged fifty-two years, entered the hospital February 24, 1899. Married twenty-three years; four miscarriages. Her father died of Bright's disease. After May, 1898, no flow for six months; then she flowed for

six days profusely. Several hemorrhages since then. Nausea and vomiting and dizziness. Lost thirty-eight pounds since November, 1898.

Diagnosis.—Fibroid of left horn of the uterus.

Operation, March 20, 1899. Vaginal hysterectomy, with removal of adnexum of the right side. Angiotribe used. Recovery.

CASE XIV.—Mrs. A., aged twenty seven years, admitted to the hospital March 8, 1899. No children; no miscarriages. Menstruation irregular. The last continued three weeks.

Symptoms.—Pain in both ovarian regions.

Diagnosis.—Tubo-ovarian disease of both sides.

Operation, March 20, 1899. Vaginal hysterectomy, with removal of adnexa. Uterus hemisected. A great deal of pus escaped through the vaginal opening from rupture of tubo-ovarian abscess on the right side. Angiotribe applied to the lower or uterine segments of the broad ligament and the electric clamp to the upper. Peroxid of hydrogen, full strength, used, followed by normal salt solution for irrigation. Duration of operation, one hour and a quarter. Recovery.

CASE XV.—Mrs. R., aged thirty-one years, admitted to the hospital March 23, 1899. Married one year; no children; one miscarriage on July 9, 1898. Has had pains for many years. Has suffered for a number of years continously from menorrhagia.

Diagnosis.—Fibroma uteri.

Operation, March 27, 1899. Celiotomy. Supravaginal hysterectomy, with removal of adnexa. Angiotribe used. Ovarian stumps cauterized with electric knife. Peritoneum was stitched over the cervical stump with catgut. Time, one hour and a half. Recovery.

CASE XVI.—Mrs. N., aged thirty-one years, admitted March 15, 1899. Married ten years; two children; no miscarriages. Complains of great pain in the back and left ovarian region.

Diagnosis.—Diseased left ovary.

Operation, March 27, 1899. Posterior vaginal section, followed by removal of left ovary and tube with angiotribe. Bleeding from posterior vaginal wall, requiring suturing with catgut. Posterior opening closed with two layers of sutures. Time, one hour. Recovery.

CASE XVII.—Miss D., aged forty five years, entered the hospital March 28, 1899. No children; menstruation began to be irregular ten years ago. Has had several hemorrhages during the last two years.

Diagnosis.—Fibroid of uterus.

Operation, April 3, 1899. Vaginal hysterectomy. Angiotribe used. Tubes and ovaries were not removed. Perineum was lacerated in delivery of the fibroid, but immediately repaired. Time, one hour and a half. Recovery.

CASE XVIII.—Miss S., aged twenty one years, admitted March 27, 1899. No children. Has been flowing every two weeks for the past year. Complains of pain in the right ovarian region.

Diagnosis.—Ovarian tumor of the right side.

Operation, April 3, 1899. Celiotomy. Removal of dermoid cyst of right ovary and tube. Time, forty-five minutes. This cyst was removed through a small abdominal incision by turning the patient upon the side, drawing the tumor by large hooks close to the abdominal incision, opening the tumor with a scalpel, and extracting all the contents of the tumor without allowing a drop to enter the abdominal cavity. The abdominal cavity was filled with normal salt solution. Recovery.

CASE XIX.—Miss H., aged twenty-one years, admitted to the hospital March 29, 1899. Pain in both sides of the abdomen; severe on the left. Enlargement of the abdomen noticed first in September last. Flowing every two weeks since January.

Diagnosis.—Multilocular ovarian cyst of right side.

Operation, April 3, 1899. Cyst removed with angiotribe. The cyst was opened with patient lying upon the side. Pedicle was twisted before application of angiotribe, to make it less bulky. Time, one hour and a half. Recovery.

CASE XX.—Mrs. M., aged twenty-four years, admitted April 3, 1899. Married thirteen months; no children; one miscarriage. Irregular menstruation since marriage. No pain.

Diagnosis.—Ovarian tumor.

Operation, April 10, 1899. Celiotomy. Removal of broad ligament cyst from each side with ovaries and tubes. Both cysts were enucleated and the angiotribe applied to both broad ligaments. Recovery.

CASE XXI.—Mrs. D., aged fifty-four years, entered the hospital April 10, 1899. Widow twenty-seven years; two children, twenty five and twenty-seven years of age; no miscarriage. Fifteen years ago noticed a "lump" in the left side. Had no pain but pressure on bladder and rectum. Menstruation every three weeks, and scanty.

Diagnosis.—Fibroma uteri.

Operation, April 13, 1899. Celiotomy. Supravaginal hysterectomy, with removal of adnexa. Angiotribe used. Several bleeding points about the cervix were secured with catgut. Bladder sewed over the stump of the cervix with catgut. Recovery.

CASE XXII.—Miss R., aged forty-four year, admitted April 11, 1899. No children. Menstruation has been regular. Has had constant pain in the right side. Says a mass was discovered in the right side, low down, eighteen years previously, the size of a hen's egg.

Diagnosis.—Uterine fibroid.

Operation, April 17, 1899. Celiotomy. Supravaginal hysterectomy, with removal of adnexa. Dermoid cyst of right side. Later, sewed over the stump of the cervix. Angiotribe used. One or two oozing points were tied with fine catgut. Time, one hour and a half. Recovery.

CASE XXIII.—Mrs. McA., aged thirty years, entered the hospital April 4, 1899. Married ten years; no children; no miscarriages. Menstruation irregular since December, 1898, flowing every two

or three weeks. Constant pain in back. Mucopurulent discharge.

Diagnosis.—Retrodisplaced, adherent uterus, with diseased adnexa.

Operation, April 24, 1899. Celiotomy. Vaginal hysterectomy, with removal of adnexa. Angiotribe used. Time, forty minutes. Recovery.

Case XXIV.—Mrs. F., aged forty years, admitted April 4, 1898. Married ten years; two children; no miscarriages. Pain in the pelvis and back. Menstruation regular.

Diagnosis.—Double pyosalpinx, with septic uterus.

Operation, April 24, 1899. Vaginal hysterectomy, with removal of adnexa by angiotribe. Few small, oozing points tied with fine catgut. Time, one hour. Recovery.

Case XXV.—Mrs. W., aged thirty-seven years, admitted to the hospital April 26, 1899. Married seventeen years; no children; no miscarriages. Mass on left side first noticed six years ago. Complains of pain in the left side. Mucopurulent discharge after menstruation. Menstruation regular.

Diagnosis.—Fibroma uteri.

Operation, May 1, 1899. Celiotomy. Hysterectomy, with removal of adnexa. Angiotribe used. Bladder sewed over stump with catgut. Recovery.

Case XXVI.—Miss K., aged fifty years, admitted April 25, 1899. No children.

Symptoms.—Had been flowing profusely for five years.

Diagnosis.—Multiple uterine fibroids.

Operation, May 15, 1899. Celiotomy. Hysterectomy, with removal of adnexa. Dermoid cyst of right ovary. Angiotribe used. Recovery.

It is not strange, when we consider the really startling character of this innovation upon what may be called "well-established principles of surgery," that there should be aggressive opposition to it and a hesitancy to make use of it by some of the very best men. In reviewing the arguments pro and con it will be well to take up first the objections to the instrument itself and the method, and afterward the advantages in its favor.

The Objections.—What I have to say here is practically in answer to questions that have been constantly propounded to me at my clinic at the Woman's Hospital.

Objection is brought to the weight and apparent clumsiness of the angiotribe. My experience has taught me that arguments on this score have no force. It requires but a short experience to convince one that the instrument can be used with accuracy and dexterity.

It has been objected to theoretically, by those who have not used it, that it is inapplicable in cases of small vaginæ. In several of my cases of vaginal hysterectomy the vagina was very small, and I feel that I can state with positiveness that it would be difficult to find a case in which the operation of vaginal hysterectomy was indicated in which the instrument could not be used. In several of the cases reported here the perineum was torn but was immediately repaired and healed.

On the other hand, I can imagine a case of uterine fibroid in which it would be next to impossible to use the instrument after abdominal section. But it must be remembered that universal application is not claimed for it, and it should not, then, for that reason be condemned *in toto*. To my mind it is applicable to the large majority of cases.

Advantages of the Angiotribe.—In order to bring out clearly the salient points of advantage over other methods, it is only necessary to place them alongside of each other in comparison.

Let us begin our comparison with the ligature, of whatever material. I am, of course, arguing on the basis of equal familiarity with all methods. In vaginal hysterectomy the angiotribe is applied with great ease, while there is more or less difficulty with the ligature, and especially in cases in which the vagina is small. The angiotribe leaves a small, flat, ribbon like stump, which in a few days sloughs away, with very little discharge and odor. The stump left by the ligature is necessarily quite large and often requires weeks to slough away, often giving rise to a secondary sepsis by blocking the way for drainage. The objection to the catgut ligature is, of course, not as great as that to silk. The former will dissolve and come away, while the latter often has to be cut away after weeks. I am happy to believe that there are but few surgeons who still use the silk ligature, either in vaginal or abdominal work. It is best relegated to oblivion.

In comparison with the clamp, left *in situ* for from thirty-six to forty-eight hours, the angiotribe stands out preeminent. With several clamps on the uterine and ovarian stumps, pressing and dragging upon the intrapelvic nerves and projecting from the vagina, to be pressed against and jarred, the torture is extreme. One or two clamps on ovarian stumps do not cause excessive pain, and can be endured. Beyond this the stump left from the pressure of the ordinary compression forceps is larger, and takes a longer time to slough away.

In comparison with the electric clamp I can see no advantage in favor of the angiotribe save that of less expense and less difficulty in application. The results from each are about the same. After the use of each there is comparatively no pain, little sloughing, and the convalescence is very rapid. Before the end of the third week the vaginal vault is, as a usual thing, entirely closed.

Though I consider the angiotribe a step in advance

of the electric clamp, I have come to the conclusion that it is better and safer to apply the latter to the upper or ovarian portion of the broad ligament when there are pus-tubes. It so thoroughly shuts up the lymphatics and renders the stump so aseptic that there is no danger of septic absorption or reinfection. I have, however, used the angiotribe frequently in just such cases, and with success, as appears in my report of cases. I merely mean that I deem the electric clamp safer as regards a secondary infection. This instrument, as well as the other high compression forceps of Doyen and Thumin, were designed particularly and chiefly for vaginal work, and have been but little used for hemostasis after celiotomy on the other side of the ocean. I have found it just as serviceable and just as satisfactory in my abdominal work, and am making constant use of it. Here it compares as favorably with all other methods as it does in operations through the vagina.

Many who look unfavorably upon this method for abdominal work have supposed that the tissues would be so thoroughly crushed that necrosis and sloughing would necessarily be the result. In fact it is, I repeat, not a crushing, but a compression. All these tissues are revitalized as after the use of the electric clamp. Thumin has taken a specimen of the compressed tissue, and, after hardening it in alcohol, examined it under the microscope. He found the tissues not crushed, their integrity not destroyed, but merely compressed to a paper-like mass (see *Centralblatt für Gynäkologie*, February 4, 1899).

Precautions.—In the course of my experience with the instrument and study of its effects and results there are many points that I have noticed that appear to be worthy of remembrance, and they are answers to questions that any one would naturally ask in watching the use of the instrument.

It is found to be most important to manipulate the stumps just as little as possible after removal of the angiotribe, for fear of disturbing the clots that are forming closer and closer attachments in the blood-vessels.

It is advised to apply the compression at right angles to the course of the vessels. The clots form more securely if this is done.

The instrument should not be applied too near the outer extremity of the broad ligaments, where the pressure upon the arteries is the greatest. It is better to apply the instrument with the patient in the horizontal position, as when the table is moved suddenly from the Trendelenburg to the horizontal, an immense pressure is brought to bear upon the clots in the severed arteries in the stumps, and there is thereby greater likelihood of hemorrhage. I observed this after using the Thumin instrument in one case, and had to resort to catgut ligatures. If in any case the Trendelenburg position has to be maintained to facilitate the application of the instrument, the resumption of the horizontal position should be only gradual, that there may be no sudden increase of pressure.

It is important that the instrument should be carefully and accurately made. If the details I have mentioned above are not carefully carried out in its manufacture failure with it is likely to occur.

I believe I am responsible to some degree for the failure of one of my confrères at the Woman's Hospital, in which the abdomen had to be opened for hemorrhage. Instead of the French instrument, he used the first copy made by Stohlmann, Ptarre & Co., and which I condemned immediately thereafter for its imperfect construction. It was clearly the cause of his failure.

I have made use of Thumin's instrument in a few cases only, and am conscious that my experience with it is not adequate enough to decide upon its merits. I feel quite positive, however, that it does not afford as much pressure as the angiotribe of Tuffier; but I am not persuaded that a pressure of three thousand pounds, which Tuffier claims for his instrument, is really necessary. I have seen good and successful work done by an instrument invented by my associate, Dr. J. D. Bissell, which I am sure produces far less pressure. I have been in the habit for many years of cauterizing the stump of the ovarian section of the broad ligament, both as an antiseptic measure and to prevent subsequent adhesions. I still continue to apply it after the use of the angiotribe, for the same purposes and not as a hemostatic precaution, though it may add something to the opposing strength of the clots in the vessels.

There is one point worthy of careful attention: I have seen no case of crural phlebitis follow the use of the angiotribe. I have been led to attribute this calamity to catgut in some of my cases. For this reason I have abandoned the use of the larger varieties, as we can never be sure that the sterilization has reached their center, and now make use of the very small varieties sterilized by koumol. They are usually very strong, bearing a great deal of tension.

There appears to be no danger of disturbing the clots in the arteries by the ordinary movements necessary in transporting the patient from the operating-table to her bed; and even excessive and prolonged vomiting seems to have no deleterious effect.

There is a marked contrast between the patients operated upon in this way and those upon whom the clamp has been used in the first twenty-four hours.

The almost total absence of pain and the absence of almost every indication that a severe operation has been performed, is the rule after the use of the angiotribe.

Conclusion.—Like anything radically new and startling as is this method, it is natural, as I have said, that it should meet a great deal of defiant antagonism and opposition. There are now, however, on record enough successful cases, both here and abroad, to answer triumphantly all adverse criticism. Landau of Berlin reports more than seventy cases; Thumin, his assistant, nearly as many, both from the use of the Thumin instrument. Tuffier of Paris reported twenty-seven, but this is but a small proportion of his total number up to the present date. There are others also in Paris who are using the angiotribe successfully.

In this country the method is now being extensively tried and good results reported. In fact, the favorable impression already made is spreading everywhere. It is difficult even to supply the instruments fast enough. I believe it is a method that will abide for all time, as it is based on solid and scientific principles.

THERAPEUTIC NOTES.

The Use of Nitrate of Silver in Eczema.—Jugeat (*Gaz. Heb. de Med. et de Chir.*, July 30, 1899), who has made an especial study of the use of nitrate of silver in the treatment of different forms of eczema, finds that it is indicated in all weeping eczemas whether subacute or chronic, and especially in those which have an external origin. It is particularly useful in eczema of the hands It fails in acute eczema especially if complicated by secondary infection, in squamous eczema, and in eczema of the scalp. He does not recommend its use in children. It works well in producing an inflammatory reaction in torpid lesions but its chief value is in the treatment of weeping eczema. In this stage, thanks to its astringent action, it causes contraction of the vessels, tones up the skin, dries the tissues, and so hastens the restoration to the normal condition. When the origin of the eczema is evidently only internal, the effects of the nitrate of silver are unreliable, so that it is necessary to institute at the same time an appropriate internal treatment. If secondary infections are present the treatment should be at first directed to their relief and afterward the nitrate of silver may be applied. Crusts should be removed so that the remedy may act directly upon the tissues. Solutions of different strengths are used according to circumstances, varying from 1 per cent. to 20 per cent. In order to prepare the surface for the nitrate of silver, it is well to apply compresses wet with sterilized water and covered with rubber tissue for twenty-four or forty-eight hours. These should be renewed morning and night during this time. Crusts may be rubbed with olive oil and removed at once. Bits of absorbent cotton, dipped in the nitrate-of-silver solution and held in a pair of forceps, are used to make the cauterizations. If pain is likely to be great or the patient is timid it is well to make a previous application of cocain, It is possible to hasten reduction of the silver, by rolling a pencil of pure zinc over the surface. Immediately afterward the zinc should be cleaned with sand-paper in order to preserve it. The zinc accentuates the action of the nitrate of silver. It is especially useful in ulcers, mucous plaques, and flat condylomata. After a few moments compresses wet with sterilized water should be applied and covered with rubber tissue. This is necessary to prevent the formation of crusts. The moist dressing should be renewed daily while the applications of nitrate are to be made every second day or, in some cases, every third day, although forty-eight hours is generally the best interval. On alternate days, instead of a reapplication of the moist dressing, a salve consisting of equal parts of simple lead plaster and vaselin may be used. The nitrate treatment is to be continued until all signs of inflammation disappear, after which an ointment of zinc oxid is indicated. If at any time the cauterizing effect appears inefficient, the strength of the solution should be progressively increased. It requires considerable judgment to know when to discontinue the application of the nitrate. As soon as the new epidermis appears, the wet dressings should be given up and the ointment of oxid of zinc should be applied unless one prefers to make use of the following formula:

℞	Zinci oxidi Amyli Vaselini	aa		ʒ iv ʒ j.

Bathing is bad and the use of soap should be absolutely forbidden. The skin is sufficiently cleansed by the moist compresses and at the time the dressings are changed.

Removal of Tapeworm by Injection of Morphin Directly into the Parasite.—Kime (*Medicine*, September, 1899) says that failure to secure the head of a tapeworm is often due to the fact that the parasite is carried into the lower bowel and has time to re-attach itself before its body is expelled. Beyond the sacrifice of a few feet of its lower end it is as well off as before. His practice therefore is to ligate the protruding part of the worm about three inches from the anus of the patient, and then to inject half a grain of morphin directly into the substance of the worm. After a short time a large injection of water is given the patient and the upper portion of the worm will pass out entirely motionless and apparently dead. Most tapeworms have a pair of longitudinal vessels extending from one extremity to the other, so that a substance injected into any segment will reach every portion of the parasite. Kime says that an elaborate preparatory treatment of the patient is quite unnecessary. His patients do not eat breakfast and about nine o'clock receive a dose of infusion of pomegranate or, what is far better, of pelleterin tannate with one or two drops of croton oil. The patient should remain in bed under the personal observation of the physician for two or three hours until movements of the bowels occur. If the worm passes, well and good. If only a part protrudes, morphin should be injected into the worm.

THE TREATMENT OF TYPHOID FEVER.

The recent discussion on typhoid fever before the New York State Medical Association, of which we publish certain of the papers this week, and others in abstract, while it does not develop anything startingly new, serves to render more definite our present knowledge of what has been well called "the great endemic disease of the present epoch of our civilization." Dr. Osler's paper drives home two very practical and valuable lessons, to the demonstration of which so much of his time in recent years has been devoted. His insistence on the fact that typhoid without abdominal symptoms is much more common than is thought, is at length having its influence in a more careful attention to diagnosis. His doctrine of the non-occurrence of typhoid fever and malaria simultaneously in the same patient, and its corollary that continuous fever, especially at the North, is practically always typhoid, are gradually being recognized as the most distinct advance in epidemiology in our day.

The treatment of typhoid is becoming ever more and more hopeful. Hospital death-rates beyond ten per cent. are now very unusual. Specific treatment of the disease is in no wise accountable for this. Much has been said of the influence of intestinal antiseptics, so-called, in aborting the disease during the first ten days, but at this time, as is well known, the typhoid bacilli that are doing their fatal work, are not in the intestinal lumen, but in the lymph passages of the intestinal walls, and antiseptics within the gut absolutely fail to reach them. The lessened death-rate has come from symptomatic treatment, which is steadily being brought into practical shape by contributions of the most varied kind from sources surgical and medical.

At present about one-third of the deaths from typhoid fever are due to intestinal perforation. One-fourth of these at least, even under present conditions, can be saved by surgical intervention. The statistics of post-perforative operation are constantly improving. It is probable that within a year or two thirty-three per cent. or more of these cases will be saved. The possibility, suggested by one authority on the subject, of recognizing with a certain degree of assurance a preperforative stage opens up a vista of still more notable improvement in typhoid mortality. About one-fifth of the present deaths from typhoid fever is the result of hemorrhage. Undoubtedly here, too, surgery will come in effectually to aid medical treatment, which is practically helpless in severe cases.

The remainder of the deaths from typhoid occur from complications and exhaustion. Many of the complications are undoubtedly due to the long febrile condition of the patient and to his insufficient nutrition. Of special interest, because it seems to promise a distinct reduction in the mortality from this cause, is Dr. Shattuck's plea for a more liberal diet than has been given heretofore. Dr. Shattuck allows his patients in the wards of the Massachusetts General Hospital what is called the soft-food diet. It includes soft-boiled or raw eggs, finely minced meat, the soft parts of raw oysters, soft puddings, soft toast without crust, wine jelly, bread without crust and milk, or crackers and milk. With this diet he has found during five years of experience no special tendency to any of the complications that might supposedly be looked for from a mixed non-liquid diet. On the contrary, the general condition of the patients has been better, complications

and relapses have been diminished, and the death-rate is less. These conclusions need confirmation from other observers, but the outlook for a distinct advance along this line is most promising.

What is needed while we wait for a specific biologic remedy for typhoid, which may not come, is more accurate diagnosis and more acute continuous observation that will anticipate the occurrence of complications. The Widal test, positive, often, only after the fever has subsided in abortive cases, will restrict still more than it has done in recent years the number of cases of so-called continuous fever that are at present suspiciously indefinite. Proper treatment and care here will lessen the number of deaths from complications, for perforation and fatal hemorrhage are not unknown in these short cases even after all symptoms have disappeared. Despite all we have thought to have accomplished in recent years, however, in reducing the mortality from typhoid fever, the statistics of a large institution like the Massachusetts General Hospital, even when all allowances are made, show no improvement in this respect during the last decade of the present half-century over that of its first decade.

CAN WHITE MEN LIVE IN THE TROPICS?

A writer in the *British Medical Journal* is much distressed because Benjamin Kidd, the author of "Social Evolution," has recently published a series of articles attempting to show that it is impossible for white men to become acclimatized in the tropics. So sure is Kidd of his position in the matter that he predicts that "in the end there can hardly be room for any important difference of opinion." He also speaks of the innate unnaturalness of every attempt to reverse by any effort within human range the long slow process of evolution which has produced such a profound dividing line between the inhabitants of the tropics and those of the temperate regions." This is decidedly dogmatic and, moreover, his pessimistic opinions are quite at variance with evidence brought before the Royal Geographical Society last April by Dr. Sambon to show that the causes of disease, deterioration, and deaths in the tropics are due to pathogenic germs, which have their limited and peculiar geographical areas, and differ greatly in the various tropical regions. If heat were the difficulty in the way, of course acclimatization would be altogether hopeless. "There appear to be good reasons, however, to believe that the real enemy is the microbe; and, if so, we may hope to fight against it in the tropics as successfully as has already been done in the temperate zones by sanitation and the gradual acquisition of immunity. This doctrine is strongly supported by some of the highest authorities in tropical pathology."

Dr. Manson, who has written a book upon this subject, and Dr. Rho, director of the Medical Department of the Italian Navy, are also thorough believers in the possibility of tropical acclimatization. "The death-rate of European troops in the tropics, which used to be from 100 to 129 per 1000, is now as low as 12 per 1000 in India. In Trinidad and Barbadoes the sickness and mortality among European soldiers are actually less than at home. The Boers are the finest men in South Africa. The Portuguese under unfavorable social conditions have been totally absorbed in India, but in Guiana and Brazil they have thriven remarkably well. Spaniards and Italians have become completely acclimatized in the tropical parts of both North and South America. The death-rate of Spaniards at Cuba is less than in Spain, and their birth-rate is greater." Unfortunately, the question has heretofore been discussed mostly by geographers, statesmen and journalists. Now that the attention of medical men is turned to it there is every reason to believe that the conditions for successful life in hot climates will become more thoroughly understood. It is to the microbe of the tropics rather than to the heat that attention should be directed. The different experiences of the men in ships and the men on land at Santiago, proved this beyond question. We have annexed leprosy in Hawaii, yellow fever in Cuba. If we expect to do justice by the tropical islands which have so suddenly come into our possession we must learn to live on them. This is the immediate problem of the medical department of the government.

ECHOES AND NEWS.

Rabies Subsiding about Buffalo.—State Agent M. Quigley, of Buffalo, stated on November 1st, that the cases of rabies in Erie and Niagara counties are being steadily stamped out. He accords considerable praise to the

police of the city of Buffalo for their effective work in capturing and muzzling rabetic dogs.

The Loomis Sanitarium Fire.—Although the administration building of the Loomis Sanitarium was totally destroyed by fire on October 14th, the work of the Institution has gone on uninterruptedly, the Casino Building having been temporarily adapted to the purposes of administration. It is expected that a new administration building will be completed within a few months. None of the patients' cottages were at all injured by the fire.

Board of Managers Defied.—On October 31st the Board of Managers of the New Jersey Custodial Asylum passed a resolution requesting the resignation of Dr. M. Alice Brownell, the asylum's resident physician. It was declared that there was friction between the Superintendent, C. W. Winspear, and Dr. Brownell. The doctor, who has held her present position for eight years, declares she will not resign until forced to do so by a higher authority than the Board of Managers.

The Rules and Regulations of the Thirteenth International Congress of Medicine to be held in Paris, 2-9 August, 1900.—All doctors of medicine may become members of this Congress by making the proper application and paying Five Dollars. The Secretary-General in Paris has instructed the American National Committee to receive the applications of American physicians and to return a receipt for the amounts sent. These applications and the money are then to be forwarded to Paris, and in due time cards of admission to the Congress will be distributed to all subscribers. Members desiring to present papers, will forward them to the Secretary of the Section to which they belong, for each Sectional Committee reserves the right of drawing up its own working program.

The Sanitary Condition of Puerto Rico.—The Board of Health of Puerto Rico notified the Secretary of the Treasury, under date of October 23d, that there was at that time not a single case of smallpox on the island. Nine months ago a serious epidemic was threatened and the disease prevailed over the whole island. Since then 800,000 vaccinations have been performed. It is possible to stamp out smallpox in Spanish-American countries. There has not been a case of yellow fever all summer. No serious diseases have followed the hurricane of August 8th. The process of vaccinating practically the entire population of Puerto Rico is graphically described in a communication we have just received from George G. Groff, M.D., of Puerto Rico. It will appear shortly in our columns.

Dr. Edward F. Brush of Mount Vernon is known generally to the profession as the quiet and unassuming producer of pure milk for babies and invalids, and no one except perhaps his most intimate friends suspected him of delighting in chasing the deer or facing the wild beasts of the forest. Rumor has it, however, that he has just returned from a hunting expedition in Northern Canada. At the head of the Ottawa Lake the doctor shot an immense moose, which stood seven feet two inches in height. He weighed 1500 pounds, and was one of the largest animals of his kind on the continent. The head is an unusually fine one, the antlers measuring fifty-eight inches from tip to tip. Dr. Brush has decided to present the head, when mounted, to the Academy of Medicine as a decoration for the banquet hall.

Death of Dr. Woodbridge.—Dr. Luther Dana Woodbridge, professor of anatomy and physiology since 1884 in Williams College, died suddenly on November 3d, at his home in Williamstown. He was but forty-nine years old. Graduated from Williams College in 1872, he became an instructor in Robert College at Constantinople for a year, after which he returned to Williams College to take the position of instructor of gymnastics. Shortly afterward he went to the New York College of Physicians and Surgeons, and after his graduation and an interneship in Roosevelt Hospital he studied abroad. Besides his work at Williams College he lectured in the Boston College of Physicians and Surgeons on "The Nervous System and Its Diseases." He was widely known in Berkshire County for his public spirit and many deeds of kindness and charity.

Johns Hopkins' Exhibit.—The exhibit of the Johns Hopkins University, including that of the Medical School, for the Paris Exhibition, is being prepared under the direction of Mr. Nicholas Murray, librarian of the university. This exhibit will form a part of the educational exhibit of the United States. The university has been asked to send articles relating to its scientific publications; to its work in the physical laboratory as illustrated by the spectrum maps, and the celebrated concave gratings of Professor Rowland; to work in geology as shown by the surveys; and to work in the biological sciences, especially in anatomy, physiology, and pathology. In this last division will be included the Medical School's exhibit. It will consist of plates illustrating the work done in the laboratory courses and of publications reporting the school's original investigations. The *Johns Hopkins Hospital Reports*, now in the eighth volume, the *Hospital Bulletin* now in the tenth volume and the *Journal of Experimental Medicine*, edited by Dr. William H. Welch, will be exhibited.

The Dangers from Infectious Diseases in Public Libraries.—The danger of infectious diseases being acquired through the books of public libraries, especially circulating libraries, has been under consideration for a number of years. The recent report of the deaths from consumption of several clerks who had been engaged in sorting old files of books and MSS., is a practical demonstration that forces upon the guardians of public libraries grave responsibilities and additional duties. Experiments have been made looking to the discovery of the best method of disinfecting books; a method that would be efficient, and at the same time not injurious to the volumes subjected to the disinfectant. The MEDICAL NEWS August 8, 1886, published a series of experiments showing that formalin was the agent par excellence for use in this work. It neither discolors articles subjected to its action

nor does it render them more liable to the corrosive action of time. On the other hand, it renders articles subjected to treatment entirely clean. The time has come, therefore, for all public libraries to have attached to them a disinfecting plant where all books, pamphlets, magazines, or documents that have been taken from the library may be thoroughly disinfected before being returned to their shelves.

The Probable Discovery of the Active Principles of Diphtheria Antitoxin.—Dr. W. H. Park present for Mr. J. P. Atkinson, assistant chemist in the Bacteriological Laboratories, Department of Health, City of New York, a solution of five different globulin precipitates obtained from diphtheria antitoxic horse-serum by means of heat and saturation of a solution of globulin by means of sodium chlorid. The solution of antitoxic horse-serum is first saturated with magnesium sulphate and the globulin thus precipitated. This globulin contains all of the antitoxin. The globulin is then dissolved in water at the room temperature and saturated with sodium chlorid. A precipitate of globulin occurs. When the temperature is gradually raised to 72° C. four more precipitates of globulin occur. Each of the precipitates has antitoxic properties, and together they contain all the antitoxin. The interest in these experiments lies first, in the method of obtaining the five precipitates from the globulin solution by saturation with sodium chlorid and moderate increase of temperature; second, in bringing antitoxin and globulin so close together that it almost seems necessary to consider antitoxin a globulin, and third the opportunity to use these antitoxic precipitates separately in the treatment of diphtheria and thus, in all probability, do away with the deleterious results, such as rashes, which now occasionally follow its use.

The Yellow Fever Situation toward the end of last week and the beginning of this was not so favorable as before. New cases were occurring at Miami in Florida and the death-rate was above the average. From Key West authentic reports were very encouraging. Reports to Surgeon-General Wyman of the Marine Hospital Service indicate that the yellow-fever epidemic which has prevailed at Key West for the past six weeks has about run its course. Only one or two new cases a day are now reported, and the messages say that a good breeze has been blowing for the past two weeks, which, it is believed, has had a beneficial influence. The reports also are to the effect that the detention hospital at Dry Tortugas has been closed because of the absence of patients. From Havana the reports for October show an excellent state of affairs in the matter of yellow fever for this season of the year. The official report is very satisfactory. The climatic conditions that existed during the latter part of September having unexpectedly continued throughout October, Surgeon Major Davis hopes that the fear regarding yellow fever will not be realized. During October there were sixty-three cases under treatment belonging to that month, with twelve cases which held over from September. Of this total of seventy-five, twenty-six recovered, twenty-five died, and twenty-four are still in the hospital. Thirty-six of the patients were Spaniards, of whom fifteen died, and twenty were Americans, of whom eight died.

The Plague Situation is in many respects constantly growing worse and becoming more threatening for the West. Alexandria is free, Hong Kong and the China Coast are announced as practically rid of the disease, in India the conditions are all improved, the only sad feature being the report of more deaths of Europeans at Poona, where, however, the disease seems to be gradually disappearing. At Oporto the condition of things is becoming more and more alarming. It seems clearly settled now that the suspicious cases reported from Asuncion in Paraguay were genuine cases of plague. Since then, occasional cases have occurred, and the authorities are not very hopeful of getting rid of the disease soon. Last week suspicious cases occurred at Santos, the port of San Paulo, south of Rio Janeiro, on the Brazilian Coast. It was definitely announced at the beginning of this week that at least twelve of these were cases of true plague. Further cases, making the number to date about twenty, have developed. The disease is of a mild type and so far no deaths are reported. President McKinley has directed the detail of Passed-Assistant Surgeon James A. Nydegger and Assistant Surgeon John F. Anderson of the Marine Hospital Service to serve in the offices of the United States Consul at Cadiz and the United States Consul General at Barcelona, Spain, respectively. The officers will assist the Consuls who are now enforcing the quarantine regulations of the Treasury Department to be observed at foreign ports by vessels bound for the United States, and will sign the bills of health with the Consuls. From these two ports these officers will have surveillance over emigration from Spain and Portugal. Practically all the emigration from Portugal, where plague prevails in Oporto, comes through Spanish ports.

MEDICAL MATTERS IN NEW YORK.

SMOKE ORDINANCE AMENDED—YELLOW FEVER ON A TRANSPORT—DEATH OF DRS. DRURY AND PARDEE—SURGEON OF ST. MARY'S ACCUSED—ALIVE IN A MORGUE BOX—REPORT OF MONTEFIORE HOME.

ON November 1st the Board of Health amended Section 134 of the Sanitary Code so that it now provides that no owner, lessee, or tenant shall cause or allow the discharge or escape of any smoke, cinders, gas, or offensive odors. Before the section was amended it simply declared that the offense should not be committed, but did not fix the responsibility. The section was further amended by striking out the conditional clause, "unless by special permit of the Board of Health," after the clause prohibiting the use of furnaces that do not consume their own smoke and gases.

The transport "Kilpatrick" arrived on November 4th from Havana and Matanzas, having on board discharged and furloughed soldiers, "indigent Americans," and military prisoners to the number of eighty-five, all told. On October 31st, when one day out from Havana, George

W. Powell, a discharged soldier, fell ill of yellow fever. He died on November 1st, and was buried at sea. The transport was disinfected, and her passengers were held at Quarantine until November 6th.

Dr. Alfred T. Drury, one of Brooklyn's oldest physicians, died on November 1st. He was born in Hull, England, and was sixty-nine years old. In 1859 he came to this country, and was graduated from the Castletown (Vermont) Medical College four years after. He came immediately thereafter to Brooklyn, where he practised until his death. Dr. Charles I. Pardee died suddenly on November 3d, at his home, No. 6 East Forty-third street. Dr. Pardee's special work was in eye and ear diseases. He was Dean of the New York University Medical School for many years. He was a member of the Union League, the New York Yacht and the Lotus Clubs. He was vice-president of the latter for eight years between 1872 and 1888. The New England Society and the Loyal Legion also claimed him as a member.

Dr. John Griffin, Chairman of the Nautical School Committee of the Board of Education, has begun an investigation of the complaint made recently to the committee by Mr. John C. Cruger of Brooklyn concerning his son's treatment while a pupil in the schoolship "St. Mary's." According to their complaint, Dr. Smart, the ship's surgeon, neglected to give young Cruger proper treatment when he reported sick. Typhoid fever developed. It would seem Dr. Smart did not make an early diagnosis. This is unfortunate, but not extraordinary.

Life and death played a game of "freeze out" during the twenty-four hours ending at 7 P.M. on November 1st; death won. At 10 P.M., October 31st, Mrs. Galioto gave birth prematurely—at the seventh months—to twins. The midwife in attendance, Rosa Genovese, of 33 Stanton street pronounced them stillborn. The unhappy father, at 5 o'clock next morning, wrapped them up in paper and put them in a little box, which he nailed securely, and which he then took to the morgue. Keeper Fane received the box and deposited it in the morgue refrigerator which is set apart for the infant dead. At about nine o'clock Fane was writing and Morgue Policeman Kip was smoking before the fire, "taking it easy" in the graceful manner characteristic of "the finest." Near by slept the morgue cat. Nothing more than the scratching of Keeper Fane's pen disturbed this serene atmosphere. Presently there came a weird sound from down the hallway, in the direction of the rotunda, where, in drawer upon drawer the dead "have lain them down in their last sleep." It seemed like the mewing of a kitten. Keeper Fane dropped his pen and looked aghast. Policeman Kip instinctively grabbed his nightstick. The cat became suddenly afflicted with opisthotonos, her hairs bristled, and she glared toward the rotunda. With blanched faces Fane and Kip reached the refrigerator, whence the sound emanated. It came from the box left by Galioto. This was hastily broken open, and one of the twins was found kicking and crying with all the force in its little body. Bellevue was at once telephoned, and Dr. Stern came and took the infant to the hospital. Despite all efforts the inlant gave up the ghost for good and all at 7 P.M., November 1st. It had been for three hours in the refrigerator at a temperature of 25° F.

At the annual meeting of the Directors of the Montefiore Home on November 1st the annual report was presented as follows: The receipts were $77,086.30, and the expenses $34,872.22, leaving a balance of $42,214.08. During the year 577 patients received treatment, and only eight were "pay" patients. At the close of the fiscal year there were 281 inmates.

MEDICAL MATTERS IN PHILADELPHIA.

MR. FREDERICK E. IVES ON COLOR PHOTOGRAPHY—ANOTHER INSTANCE OF EDDYISM—UNUSUAL DEMANDS ON THE MEDICAL INSPECTORS OF THE HEALTH BUREAU—A RECEPTION TO DRS. FLEXNER AND CLARKE—DR. TURNBULL'S RESIGNATION FROM THE JEFFERSON HOSPITAL STAFF.

PHILADELPHIA, November 6, 1899.

At the last meeting of the College of Physicians of Philadelphia, held November 1st, Mr. Frederick E. Ives gave an interesting demonstration of his system of Color Photography, and of its application in the field of practical medicine. Mr. Ives first gave a brief explanation of the principles involved in the process, showing the wide range of tints which could be derived from the three single colors upon which his system was based, by simultaneously projecting upon a screen three photographs of the same object, side by side, one colored red, another green, and another blue, and then by gradually superimposing and blending these three colors, obtaining finally a picture of the object in its natural colors, against a perfectly white background. Mr. Ives also showed an instrument, known as the kroemskoep, devised for examining photographs of objects in their natural colors, as one would examine a picture through a stereoscope. The kroemskoep consisted of an enclosed box, containing three plates of red, blue, and green glass, respectively, and two colored glass reflectors, so arranged that, by the aid of reflected light and a pair of stereoscopic eye-pieces the three colors become blended before the eye of the observer at a point opposite the center of the object to be examined. Thus, one is enabled to view the object in its natural tints, standing out in bold relief against a colorless background. The possibilities of Mr. Ives' method of color photography for teaching purposes, especially in the fields of pathology and surgery, were emphasized by Dr. W. W. Keen, who dwelt upon the value of the invention in enabling the student to observe tumor sections, for instance, just as they appear in the true specimen. Such conditions as jaundice, and the various kinds of cutaneous eruptions of the exanthemata and of skin diseases were also capable of exact reproduction by this apparatus. Dr. Keen expressed the opinion that, in the future, hospitals would be equipped with apparatus for the photography of various lesions after this method.

Another instance of the fatal results of too much Eddyism is illustrated by the death, at the end of the present week, of a prominent and wealthy resident of Germantown, whose story of unbelief in physicians and trust in

Christian Science is the principal topic of current discussion in the public prints of this city. The deceased, a life-long trifler with his health, had, it is understood, been under the "treatment" of various exponents of the Christian Science cult, including, as a last resort, a visitation from that arch-priestess of the sect, Mrs. Mary Baker G. Eddy, herself, who was summoned post-haste from Boston, in lieu of the more rational procedure of consulting a specialist in tuberculosis, for phthisis was the sufferer's disease, and he was sorely affected. But in spite of Mrs. Eddy's "influence" with the Power above, and so forth, and in spite of her lesser disciples' prayers and "readings," the patient grew worse, grew moribund, and finally died. That the deceased experienced intermittent periods of blacksliding from the "faith" appears to be conclusive from the two facts that he had at various times during the past summer sought the advice of a physician of high standing in this city, and that he is reported to have repudiated his Bostonese advisers as visions of the hereafter began to become more vivid; but to no avail, for he died, attended by one of the cult, a resident of this city, although a physician was called in, at the last moment, too late to be of service.

In view of the unusual prevalence of diphtheria and scarlet fever in this city at the present time, the work of the City Medical Inspectors becomes a matter of prime importance to the health of the city, and of timely interest to the general public. Other cities, as a rule, appreciate the work of these sanitary officers, and are willing to provide means for the intelligent pursuance of their labors, but Philadelphia, thanks to the present Administration's parsimoniousness toward this needful and practical branch of the municipal sanitary service, has not only reduced the number of Inspectors from fifteen to eleven, but has had the audacity to redistrict the whole city into larger areas, so that their work is increased to a degree which renders its proper performance an absolute physical impossibility. While the Inspectors are, in all good faith attempting to live up to the rules of the Health Bureau by making daily visits of inspection to at least two public schools in their respective districts, the extraordinary demands made upon their time by imperative calls to the large number of contagious diseases now prevalent, relegates the duties of school-inspection, and of the medical examination of school children to a standpoint of secondary importance, so that these duties must needs be perfunctorily observed in many instances. Each inspector is supposed to cover a district containing from 75,000 to 150,000 inhabitants, according to the density of population, and the supervision of the sanitation of such a population, which, even in times of general good health, is not a matter of play, becomes, in the present state of the prevalence of contagious diseases an undertaking which is too great for any one man. But the authorities refuse to increase the force of Inspectors, or to aid them in any way, so that some of the work must be glossed over, and a great deal of it done hurriedly, with what outcome the onset of an epidemic may unfortunately determine.

The Medical Club of Philadelphia gave a reception and dinner on November 3d, at the Hotel Bellevue, to Dr. Simon Flexner and to Dr. John G. Clarke, the two new occupants of chairs in the Medical School of the University of Pennsylvania. A large number of prominent medical men were present, and speeches were made by the two principal guests of the evening, and by a number of others.

Dr. Laurence Turnbull, for many years otologist to the Jefferson Medical College Hospital, has tendered his resignation from the staff of that institution. Dr. Turnbull's widely-known success in his specialty was largely gained in the services of this hospital, in which he originally organized and perfected the department of otology, now in a flourishing condition thanks to his interest and personal labors.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

ANOTHER DEATH AT THE DOOR OF A MIDWIFE—POISONING AND DEATH AT ALDERSHOT—IN AID OF HOSPITALS—AN INGENIOUS APPLIANCE FOR THE TREATMENT OF TINEA—A NEEDLE FOUND EMBEDDED IN THE HEART MUSCLE.

London, October 29, 1899.

The failure of Parliament to pass at its last session some effective bill for regulating the practice of midwifery is becoming more obviously deplorable every day. It will be remembered that two bills were presented, one by the so-called Midwives Association, which really rendered these interesting survivals of barbarism an independent branch of the medical profession; the other drawn up by the Committee of the General Medical Council, which went perhaps a little too far in the opposite direction, by permitting them to practise only under the direct supervision of a qualified medical man. A death has just been reported from Walthamstow of a poor woman who had been attended in her confinement by a midwife and who died six or seven days later from well-marked septicemia. The case was a perfectly typical one both in its clinical history and its post-mortem appearances, and the midwife evidently realized her culpability as she failed to appear at the trial on the ground of "serious illness." It is to be hoped that vigorous action will be taken in the case by the law officers, and attention again called to the serious source of danger which these ignorant and uncleanly representatives of "Sairey Gamp" are to the community.

The result of the inquiry into the curious case of food-poisoning among the soldiers at Aldershot to which we alluded in a former letter has been an open verdict. The case proved to be one of the most puzzling ones which has come before the experts in many months. Twenty-six men, out of one battalion, were taken seriously ill with symptoms of gastric irritation, and of these five died. The clinical diagnosis of food-poisoning was made at once, and as usual on this side of the Atlantic, American canned goods were put down as the offending cause. Indeed the Quartermaster immediately forbade the selling of canned goods of any description or of prepared pastries in the regimental canteens on the strength of this

impression. It was found, however, that no canned goods had been consumed by the men attacked within forty-eight hours, and as soon as the experts were put on the case the strong similarity of the symptoms to those of poisoning by tyrotoxicon was noted at once. Cheese had been supplied to the men as a part of their haversack rations during the maneuvers in which they were engaged, and upon examination this was found to contain abundance of tyrotoxicon. It will be some satisfaction to our injured innocence to know that the cheese was not an American but a New Zealand product. This would look like a fairly clear case, but the missing link in the evidence was that no clear proof could be found of actual ingestion of the cheese by the diseased men, nor could any ingested portions of it be found in their stomachs, or a sufficient quantity of ptomain to permit of definite identification as tyrotoxicon. A curious piece of collateral evidence was furnished, however, by the discovery that a number of sheep, ranging over the ground of the maneuvers, had died with gastric symptoms and upon examining the stomachs of some of these a considerable amount of partially digested cheese was found in them. It would therefore at least be fairly suggestive to anybody but an official Board of Inquiry that the soldiers, disliking the taste of the cheese, after swallowing only a few bits of it, had thrown it away to be picked up by the unfortunate sheep, and that those men whose gustatory nerves were least sensitive had swallowed enough of it to cause fatal results. Unfortunately most of the men were dead before the cheese was suspected, so that no definite inquiries had been made in regard to that article of diet. The suspicious feature of the verdict is that the cheese had been supplied by the Government of New Zealand directly to the War Department, and the case was most carefully watched by two or more of their official and legal representatives, so that there might have been "reasons of state" for the inability to elicit from the soldiers who recovered the simple fact whether they had eaten any of the cheese or not. Further inquiry is urgently demanded by the public press.

A graceful form of memorial, which we are glad to see is becoming more and more common, has just been observed by General Sir Francis Grenfell, one of the conquerors of the Khalifa, in sending a donation of $2500 for current expenses to the Middlesex Hospital Cancer Wing, recently erected in memory of the late Lady Grenfell.

The committee of the Royal Ear Hospital is arranging for a subscription ball next month to raise funds for a new building, the site of which was purchased some months ago. The science of skillful and ingenious begging for the best of purposes is being carried to even a higher pitch in this country than in our own, and the first "coup" planned by every new hospital is to get itself under the patronage of some distinguished member of the nobility, or, if possible, of the royal family. This results in some rather curious collocations in the title of the institution, as in this instance, in which the first glance at the name might lead to the impression that the royal ear was either so extensive, or subject to such a multitude of diseases that an entire hospital was needed for its care.

A most ingenious little appliance for the treatment of obstinate cases of ringworm was displayed by Dr. Phineas Abraham in a clinical demonstration at the London Polyclinic last week. It was born of the recognition of the fact that in chronic cases of great persistence, such as we have all had painful experience of, the principal stronghold of the tinea is not in the skin of the scalp, but deep in the follicles of the hair, into which, of course, ordinary ointments rubbed or solutions painted upon the surface of the skin could hardly by any means be got to penetrate. Its principle was suggested to Dr. Abraham by the process by which blocks for wood paving are saturated with creosote *in vacuo*. These are placed in a retort from which the air is rapidly exhausted by an air-pump, and then creosote in the form of vapor is introduced, and as the result of the "vacuum" having penetrated some distance down the tubes and fibers of the wood the vapor is literally sucked or drawn completely through and through the mass. This process is imitated in a lesser degree upon the scalp by a small bell-jar with a rubber rim, which, after the scalp has been thoroughly cleansed with alcohol and ether, is pressed upon the area desired to be treated and the air within rapidly exhausted by a small syringe pump. When the tissues have been well sucked up into the cavity of the cup a cock in the bottom of a small tube of creosote is opened and the drug, in the form of vapor, pours into the vacuolized tissues. Dr. Abraham has found it of great practical value in sterilizing not merely the surface, but even the depths of the hair follicles, and by this means alone has succeeded in curing many obstinate cases which had defied all other methods of treatment.

A new genius has arisen in the realm of hospital reform, this time with a bold and radical proposition, that inasmuch as hospitals in the heart of a great city are at an immense expense in the matter of ground, taxes and maintenance, while the patients are at a corresponding disadvantage as to light, air, and quiet, that the great mass of the large city hospitals should be removed bodily out into the country, leaving only a small receiving department and staff for attending to acute emergency or accident cases. The proposition is a Utopian one, but would, we fear, be found almost disastrously impractical both from the point of view of the patient, in his removal from work and friends, and from the point of view of both the physician and the students in attendance at the centers. The suggestor has evidently little or no practical knowledge of the nature of the great bulk of cases which come into our metropolitan hospitals. Unquestionably the establishment of a country branch and convalescent home for each of the hospitals would be a very decided advantage, and we are glad to see that some hospitals are considering this proposition. Certainly every proposal of extending the building of an already established hospital, or of building a new one, ought to be most critically scrutinized from this point of view. Much regret has already been expressed over the action of the great Brompton Hospital for Consumption in building a large and beautifully fitted addition, nearly doubling its capacity, just across the street from its original building and in the heart of a

densely populated portion of the city, instead of spending the money for a sanatorium on some hillside in the country, where the open-air treatment could be carried out with advantage.

Hospital Saturday has again come and gone, and although it will be some weeks before the results are in, yet the preliminary returns are most encouraging. The policy of the abandonment of regular personal street collections has much to recommend it, but it is still on trial and the results will be watched with much interest from this point of view. The amount raised and distributed by this means last year was a little more than $85,000. This, though apparently a large sum, is relatively small for a great metropolis and actually inadequate, as the lowest estimate of the yearly deficit in the expense account of the eleven largest hospitals alone is $100,000.

A curious cause of death was brought before one of the London coroners this week. A lady described as a Polish countess died suddenly in Islington with symptoms pointing to some form of thoracic hemorrhage. Upon post-mortem examination the pericardium was found filled with bloody fluid and a large needle was discovered embedded in the wall of the right auricle and penetrating into its cavity. By the movement of the heart it had apparently produced some laceration of the wall, permitting escape of blood, besides setting up a violent pericarditis. No history could be obtained as to the possible cause of the presence of the needle in this situation. The coroner, however, was quite equal to the emergency, and summed it up with perfect gravity as one of those remarkable cases, so celebrated in myth and legend, in which a needle accidentally introduced into some part of the body had "worked its way" through the tissues until it had penetrated some vital organ or again appeared upon the surface. The case has a curious parallel, however, in the lower animals, as a quite frequent cause of fatal pericarditis and even laceration of the heart-wall in cattle is the penetration of the sac by pieces of wire, rusty nails or needles, from the great paunch, after having been swallowed with the food. Pericarditis in the ox is commoner than in any other species of domestic animals solely upon this account. The suspicion, therefore, would appear to be strong that the case was one of suicide by the method of swallowing a needle or needles, one of which had pierced the pericardium and produced this fatal result, or it is barely possible that the needle might have been introduced directly from the surface by a determined hand. A by no means uncommon form both of suicide and murder among the ingenious Chinese is to push a large needle into the viscera through the umbilicus.

The Government has another Boer question on its hands. The unterrified Board of Leicester Guardians, after awaiting the descent of the long-delayed mandamus thunderbolt for months, now that it has fallen absolutely refuse to comply with its provisions. There are, however, some signs that common sense and prudence are making themselves heard, even in their voluminous ears, by the fact that while at the former meeting the Board was almost unanimous in its determination to court martyrdom, on this occasion there was a long discussion. In the course of this one of the Board delivered himself of the sentiment that if they did not comply "their goal would be gaol," which, spelt after the antiquated English fashion, is rather a fine bit of alliterative antithesis. When the vote was taken it stood only twenty-five to eighteen, and had it not been for the fierce appeals of one female member of the Board the scale might have been turned in the other direction.

One of the London vestries has got itself into what we hope will prove a serious scrape. The wood-block system of pavement is becoming a prime favorite in London again on account of its noiselessness and freedom from being slippery. The objections to it as being an absorbent, moisture-holding, and a culture medium for germs it was supposed had been overcome by its saturation with creosote *in vacuo*. One vestry, however, of an economical turn of mind, thought that this last item was a fad and might just as well be omitted, but unfortunately for its peace of mind the street which it chose for this exhibition of parsimoniousness was the Mecca of consultants, Harley Street, known in popular language by the undeserved term, Valley of the Shadow of Death. The loudness of the outcry that has been raised may be better imagined than described, and we think that the Board will speedily be driven to recede from this parsimonious stand not only in the case of Harley Street but also in other neighborhoods less keenly alive to their sanitary interests.

Still more encouraging reports come in from the results of the malaria commission to Sierra Leone, the pools in one malaria-soaked district, Freetown, infested with anopheles being under one hundred in number and probably capable of permanent sterilization by the service of one man with a kerosene can.

SOCIETY PROCEEDINGS

NEW YORK STATE MEDICAL ASSSOCIATION.

Sixteenth Annual Meeting Held at the New York Academy of Medicine, New York City, October 24, 25 and 26, 1899.

SECOND DAY—OCTOBER 25TH.

AFTERNOON SESSION.

(Concluded from page 608.)

THE President, JOSEPH D. BRYANT, M.D., of New York in the Chair.

DR. HERMAN M. BIGGS of New York County read a paper, entitled

THE ADVANCE IN OUR KNOWLEDGE OF TYPHOID FEVER,

which appears in the present issue of the MEDICAL NEWS.

DR. W. H. PARK of New York City read a paper, entitled

BACTERIOLOGY OF TYPHOID FEVER,

which will also appear in a subsequent issue of the MEDICAL NEWS.

DR. WILLIAM OSLER of Baltimore followed with a paper, entitled

CLINICAL DIAGNOSIS OF TYPHOID FEVER.

There is no one symptom, nor two symptoms, nor three symptoms that are always present in typhoid fever. Any or all of the usual symptoms may be absent. We do not judge by a few positive signs. The diagnosis is a rational one, and must be often made on circumstantial evidence. Yet few diseases are so certain in their diagnosis as typhoid fever. These are practically the words with which Elisha Bartlett begins his chapter on the diagnosis of typhoid fever written in the year 1842. They are as true to-day as they were then, despite all the work that has been done on the subject since.

For instance, very often we meet with cases in which for five to eight days there is slight fever, and in which we sometimes can feel the edge of the spleen. If rose spots do not develop we are apt to call them simple continued fever. In a number of cases, however, after the cessation of the fever, patients have given the Widal reaction, showing that it was really typhoid fever. A recent epidemic in Switzerland was very interesting in this particular. Some thirty cases of frank typhoid fever were treated in the hospital. Twelve other patients, who had slight headache, moderate temperature, and general malaise were not put to bed because they were considered not to have the disease. The application of the Widal test after their convalescence showed that they had had typhoid fever. The Widal test will undoubtedly greatly restrict simple continuous fever as we know it now.

Too much insistence has been given to the abdominal symptoms of typhoid fever. It is very possible for the disease to occur absolutely without abdominal symptoms. Out of thirty-five cases that have been under his care during the last month only four patients have had distinct abdominal symptoms.

Besides the enteric type there are forms of the disease in which the cerebrospinal, the pulmonary and the renal symptoms are of most importance. Many cases of sporadic cerebrospinal meningitis are undoubtedly typhoid fever of the meninges. Very often the typhoid fever is concealed by the occurrence, in the midst of a more or less continuous fever, of a consolidation of one or more lobes of one or both lungs. Undoubtedly certain cases of so called acute nephritis are really renal typhoid. The disease may run on without other symptoms until the development of rose spots betrays the nature of the disease. There may be no fever at all, or it may begin very abruptly; there may be rose spots, intestinal symptoms may be entirely absent, and so there may be no diazo-reaction. The Widal test may be positive only very late in the disease, or may not occur until after the fever has ceased. There may be no leucocytosis.

Repeated chills usually means malaria. The differential diagnosis of malaria is not so difficult as has been thought. No continued fever diagnosed as malaria here in the North in former times was probably anything but typhoid. The country was shocked during the Spanish-American war by the discrepancy of reports and the disagreement of doctors with regard to the existence of typhoid or malaria in the camps. It was not the army surgeons who were to blame, nor the profession of the country, but the teachers at our medical schools who have not insisted enough on the distinction between these two diseases. Malaria is such an accommodating word. It covers such a multitude of diagnostic sins. It was at least as consoling in its way as the unctuous word Mesopotamia, to the old woman in the story. Above Mason's and Dixon's line an intermittent fever that does not yield to quinin is not malaria. Practically only tertian fever exists at the North, and this yields readily to quinin in thirty-six or forty-eight hours. At the South we have the estivo-autumnal type which gives rise to a remittent fever. The curve reaches a fastigium and then does not vary by a degree perhaps for days. The temperature chart is like a map of the Pennsylvania Railroad; that of ordinary malaria is more like the multi serrated line of the Baltimore and Ohio. The estivo-autumnal type may resist quinin for two or three, or even four or five days. The parasite of the disease too is harder to find so that there is more reason for mistake in diagnosis. Out of a thousand cases observed at Baltimore at Johns Hopkins in only one case did malaria and typhoid occur together. In general and obscure febrile cases it is better to suspect typhoid than malaria. Our position in the matter should not be the Anglo-Saxon one of thinking the case innocent of typhoid until proved, but rather the Gallic position of considering the case guilty of typhoid until it is demonstrated to be innocent. Two works should be on every physician's table—Keen's "Surgical" and Hare's "Medical Complications of Typhoid Fever."

DR. E. G. JANEWAY of New York then read a paper, entitled

SOME INTERESTING CASES ILLUSTRATIVE OF THE PECULIARITIES OF TYPHOID FEVER.

In three cases he has seen tetany as a complication of typhoid fever. The affection is rare in this country, or rather is rarely reported. It is probable, however, that it occurs more frequently than is thought and the muscular rigidity is considered a part of the irritable muscular condition of the disease. In one of these cases the involvement of the jaw made feeding difficult.

In a number of cases he has seen psychosis develop of so severe a type that the affection has been considered to be acute mania. Typhoid-fever patients have even been sent to the asylum as insane. A suicidal tendency is extremely common and should always be carefully guarded against. Typhoid-fever patients should never be left alone. In one case in charge of a doctor the patient asked him to leave the room for a few minutes in order to make urination easier. When the doctor returned after only a minute he found the patient attempting to cut his throat. In another case in charge of three nurses, the patient asked them to leave the room because their presence disturbed her. They did so and she leaped from a fourth-story window into the area. Sharp instruments, pistols, or dangerous drugs of any kind should not be left within reach of typhoid patients.

"Some unexpected eruptions occur in typhoid fever. I have seen herpes several times, though it is so infrequent that whenever I find it in a case of suspected typhoid I

carefully revise the diagnosis and usually find that it is some other affection with which we have to deal. With herpes present the diagnosis of typhoid is very improbable. Petechial eruptions that make one think of typhus fever occur occasionally. I have seen peculiar eruptions of this kind occur beneath cold-water coils that had been placed on the abdomen. The spiral blood extravasation had sometimes alarmed the patient and his friends considerably. Once I was almost tempted to diagnose typhoid in a case in which sapremia due to suppressed menstruation proved to be the real cause of the fever and increased pulse-rate.

"In general in office practice the rectal temperature should be taken more often than it is. Patients come in out of the air and the temperature of the mouth will often be normal at a time when the rectal temperature shows distinct fever. Many patients that we treat now in our office for febriculæ would be sent home to bed if we took rectal temperatures more frequently."

DR. WILLIAM H. THOMSON of New York City followed with a paper on

STATISTICS OF TYPHOID FEVER AT THE ROOSEVELT HOSPITAL FOR TEN YEARS.

He has had in his service during the last ten years 368 cases, in 275 males and 93 females. Of these 25 have died, a mortality of 6.8 per cent. Fifty-six per cent. of the deaths have occurred within a week after admission. Most of the patients were hopelessly moribund when they came into the hospital. Only 3 per cent. of the patients who remained in the hospital for more than a week died. "The routine treatment of the hospital in my service is to give calomel and jalap every third night until the middle of the second week, sometimes even well into the third week. As diet the patients take milk, mixed with equal parts of lime water. As all pastoral peoples that live much on milk have some way of curdling it in order to save the stomach the labor of coagulation I frequently make use of this expedient. When there is much tympanites I find turpentine the best remedy. As soon as the tongue begins to become dry I give 10 to 20 minims. Since 1874 cold baths have been used in my service at the hospital. I consider that they are useful not only for the fever, but also for the toxemia. In all cases where albuminuria exists I give large injections, 4 to 6 pints, of saline solution."

DR. REGINALD FITZ of Boston read a paper, entitled

TYPHOID FEVER IN THE MASSACHUSETTS GENERAL HOSPITAL DURING THE PAST FIFTY YEARS.

The death rate by decades in the Boston Hospital during the past fifty-years has been: From 1839 to 1849, eleven per cent.; from 1849 to 1859, sixteen per cent.; from 1859 to 1869, fifteen per cent.; from 1869 to 1879, 16.6 per cent.; from 1879 to 1889, 14.7 per cent.; from 1889 to 1899, 13.5 per. cent. The mortality from typhoid fever has not improved then to any very great extent in the fifty years. There has been a definitely lessened mortality since the institution of cold-water treatment; during the last five years liquid diet has not been absolutely adhered to in one of the departments of the hospital. Patients under Dr. Shattuck's care have been allowed to take soft, solid diet, including farinaceous puddings and the like. This has given excellent results, and especially has not increased the tendency to hemorrhage. As a matter of fact, mortality has been less in this diet than with an absolute milk diet. There have been no more complications, and not any more relapses than under the more severe system. It is evident that something can be allowed besides milk.

DR. A. A. SMITH of New York read a paper, entitled

SOME PHASES OF TYPHOID FEVER AS SEEN IN BELLEVUE HOSPITAL,

which will appear in a subsequent issue of the MEDICAL NEWS.

DR. ABRAHAM JACOBI of New York then read a paper, entitled

TYPHOID FEVER IN CHILDREN.

The severity of the illness in typhoid fever in children does not always correspond to the height of the fever. At times the disease runs an afebrile course. In cerebral cases this is especially true. Cases complicated by a great deal of toxemia are also likely to have low temperatures. In general, typhoid with low temperature in children has a bad prognosis. Ambulant cases are likely to occur in children rather frequently.

Otitis occurs rather commonly as a complication. It does not often cause perforation of the tympanum, however, for the Eustachian tube is a wide-open funnel in childhood, and may drain away the inflammatory secretion. There may be two daily curves of temperature in the disease in children, so that the temperature should be taken at least four times a day, or even oftener. Gurgling in the ileocecal region should not be considered as suspicious of typhoid in children, for this symptom occurs very frequently in many intestinal affections of childhood. Hemorrhage in children, too, depends on the character of the epidemic and on the season in which the disease occurs. Some years the speaker had seen no hemorrhages, while in others they occurred rather frequently.

As to the treatment, he insisted on absolutely liquid diet until apyrexia had lasted ten days. Patients should be given plenty of water by the mouth. If ten drops of dilute hydrochloric acid be put in water and then sweetened a very pleasant, cooling drink is obtained. This serves the useful purpose of washing out the intestinal tract, of diluting the toxins in the circulation, and of causing diuresis by a rise of blood-pressure. The lips and tongue should be kept clean. The nose should be sprayed out occasionally. The position of the patient should be changed frequently in bed so as to avoid hypostatic affections of the lungs and spinal cord. Calome should not be given after the first half of the second week. For offensive stools thymol or permanganate of potash, 1 to 4000, are useful remedies. Where stimulation is needed camphor in sweet almond oil 1 to 4 parts is very useful. For excitement chloral is a useful remedy. Where there is weak heart croton chloral should be substituted.

There is a prejudice against antipyretic drugs. It has been assumed that high temperature helps to kill bacteria and increases the amount of antitoxin formed by the system. This idea is no longer generally accepted and Flügge denies it entirely. Certainly patients are more comfortable when the temperature has been brought down. Not all antipyretics are advisable. Acetanilid, for instance, is a tissue poison. It causes the formation of methhemoglobin in the blood and so is dangerous. As the old Greek poet said, water is the best. Use it for its antipyretic effect, not for any presumed stimulating qualities. It need not be used cold, for water at 90° to 95° F. will bring down temperatures of 104° to 105° F. very readily. Bathing is contraindicated when there is a feeble heart or where there is pneumonia or peritonitis.

DR. DELANCY ROCHESTER of Erie County read a paper, entitled

THE LOCAL, NON-SURGICAL TREATMENT OF THE INTESTINAL TRACT IN TYPHOID FEVER.

Nihilistic therapeutics in typhoid fever have had their day. There are a good many drugs that produce good effects. Calomel, for instance, is undoubtedly useful. It is especially to be remembered, however, that a certain amount of the typhoid lesions occur in the large intestine and in the small intestine not very far from the ileocecal valve. The ulcers in the large intestines can be reached by high rectal injections. It has not yet been definitely decided whether we can force injections under gentle pressure beyond the ileocecal valve in all cases. In some cases we certainly can. In typhoid fever the large intestine always suffers from a catarrhal condition and this at least will be benefited by the rectal injection. This local treatment of typhoid fever should not be neglected.

DR. W. W. KEEN of Philadelphia followed with a paper, entitled

TREATMENT OF PERFORATION OF THE BOWEL IN TYPHOID FEVER.

Since Mikulicz in 1884 performed the first operation for perforation of the intestines from typhoid ulcer, up to the end of 1898, eighty-three cases were operated on, and nineteen per cent. of them were saved. During this last nine months sixty-seven additional cases have been operated on, and twenty-six per cent. of them have been saved. If doctors would but remember that the healing process during typhoid fever is quite as good as in health surgeons would get more chance to operate, be called sooner to the cases, and very soon the statistics would show at least one in three saved.

In what class of cases should we operate? In practically every case. The better the general condition the better the chance. One case was operated on three times and survived. Two cases have been operated on twice. One case was operated on successfully for post-operative obstruction. In cases under fifteen years of age, where operation has been done, fifty per cent. have recovered. From fifteen to twenty-five years of age is the most unfavorable period. Women have perforations less than half as often as men, and recover twice as often from operation, according to the statistics. The later in the disease that perforation occurs the better is the prognosis.

When should we operate? Not during the primary shock. This means usually not during the first twelve hours. I have seen fit to correct this original expression of opinion, and to say rather not during the first eight hours. There would seem to be two rules: First, operate as soon as possible; but, second, do not operate during profound shock. The improvement of the statistics in the future will depend not so much on any perfection of our technic, but on advance in diagnosis. The preperforative stage has been spoken of. If this can be recognized with any assurance then, perhaps, we can prevent perforation entirely. In any case a surgeon should be called in consultation as soon as any abdominal symptoms appear that point even to impending perforation. An exploratory incision may be made under cocain anesthesia with very little inconvenience to the patient. After this exploratory incision, bacteriologic specimens may be taken and examined to see if there is any peritonitis.

The Halsted mattress suture should be used rather than continuous suture. If the perforation is very extensive, a resection of the intestine may be done. Two recoveries have been reported after such an operation. If at any point there seems to be impending perforation the spot should be sutured. Such points should be looked for carefully, as a number of cases have terminated fatally after operation owing to the occurrence of a second perforation. The abdomen should be closed without drainage. Speed is an important factor in the success of the operation. There are cases in the literature of the subject now which show that the surgeon need never despair of any case, no matter how low the patient may seem in vitality, and no matter how many other complications have occurred before. Most unpromising cases have ended in recovery.

THIRD DAY—OCTOBER 26TH.

MORNING SESSION.

DR. E. D. FERGUSON of Troy offered a resolution to the effect that since the branch association cannot constitutionally elect the vice-presidents for the different districts, that they be asked to recommend some one each year to be chosen to that office by the Association.

DR. WICKES WASHBURN of New York offered a resolution that a committee be appointed to draw up a leaflet for popular instruction as to the treatment of consumptives at home.

DR. STEPHEN SMITH explained what was being done by a committee appointed to guide legislation as to the establishment of a national bureau of health. He explained what was proposed by the Spooner, McCaffrey, and the Hepburn bills, and asked that the Association adopt a resolution recommending to Congress the passage of the Spooner bill, which creates a special bureau of public health in the Department of the Treasury.

All of these resolutions were adopted by vote of the Association.

DR. HENRY O. MARCY of Boston then read a paper with the title

TWO CASES OF LARGE RETAINED HERNIA OPERATED UPON WITH FATAL RESULT.

The speaker has had two unsuccessful results which he thinks will be of service to his colleagues to have knowledge of, as they seem to indicate that size of the hernia alone, when it is excessive, may constitute a contraindication to radical operation. The first case was that of a man weighing 250 pounds, six feet in height, and not over stout. There was a retrocession of the abdomen below the umbilicus. He had a right inguinal hernia, the tumor of which reached almost to the knee. It proved an operation effecting almost the whole of the large intestines, and several feet of the small intestine. The mesentery had become extremely thickened, by actual measurement being more than two inches in thickness. There were no adhesions. The patient was placed in a pronounced Trendelenburg position. After the opening of the sac the intestines were gradually pushed back into the abdomen. The abdominal walls relaxed well, and the intestines went back without difficulty. It was very hard to get all the mesentery back, but this was finally successfully accomplished. When the wound was closed the abdominal walls did not seem over tense. The patient had taken the anesthetic very well, but began to cough severely almost immediately on coming out from its influence. A large amount of frothy mucus was coughed up. Death ensued thirty-two hours after, evidently from interference with pulmonary function, though no special lesion developed.

The second case was that of a man aged fifty-two years, a prominent educator in the West, who had a very large tumor due to a right inguinal hernia. He was six feet two in height, and weighed 350 pounds. Despite this large weight he did not have the appearance of being too fat. His hernia had developed many years ago, as a result of riding in the mountains, and could not be retained by a truss. When it became very large it was supported from his shoulders in a bag arranged for the purpose. It became strangulated twice. And each time relief was obtained only with the greatest difficulty. It was extremely painful and gave a sense of continual discomfort, even while he was in bed. He realized all the dangers of the operation, yet felt that life was not worth living in his present condition. On examination his scrotal hernia proved to reach nearly to his knee. The operation was done without much difficulty. After the incision of the sac the omentum proved not to be very much thickened, the appendix was extremely lengthened and hypertrophied. It was at least six inches long and as thick as the index-finger. The cord was very long from the opening in the abdominal wall to the testicle being at least twenty inches. It was very interesting to see how completely the dartos contracted after operation. The intestines presented some difficulty in getting back at first, but the resistance suddenly yielded and their replacement was easy. After coming out of the anesthetic his respirations rose from sixteen to forty. His pulse rose to 140 and his temperature to 102° F. The next day his temperature and pulse came down, but the respirations continued as frequent as before. There was no nausea, after a day or two he digested well and he slept well. His respirations continued rapid until the ninth day, when he died suddenly. The autopsy proved absolutely negative. Nothing could be found to account for the death.

There are no such cases as this mentioned in medical literature so far as I have been able to ascertain. I have operated on large tumors and have not considered size as a contraindication to radical operation for hernia. It is evident, however, that this must be given careful attention in all such cases.

The next paper was read by DR. WILLIAM S. MACLAREN of Litchfield, Conn., and was entitled

THE SPHERE OF DRAINAGE IN SURGERY OF THE APPENDIX.

He thinks that drainage is not only useless but harmful after operation for appendicitis. Appendicial abscess should no more be treated as an ordinary superficial abscess than should an ulcer of the stomach be treated in the same way as an ulcer of the leg. The use of drainage introduces a factor on the wrong side. Irritation is set up where inflammation existed before. If a glass tube is used it is practically a foreign body and causes a similar reaction. Gauze drainage is irritant just in proportion to the amount of gauze used. Even in septic cases the best treatment is to leave the abdomen filled with saline solution and close up the abdominal wound completely. The use of saline plentifully dilutes the toxins present in the peritoneal cavity, and spreads the septic material over a large amount of peritoneum. Now each square inch of peritoneum is capable of destroying a certain amount of infectious material. When the virus present, whether chemical or biological, is spread over a large surface the resistive vitality of a large number of cells is called into action, and the result is final victory over the morbific agent. In a recent case in which an appendicial abscess had ruptured into the peritoneal cavity the incision of the peritoneum was followed by the exit of foul smelling pus. This was not walled off and general peritonitis seemed already in progress. Eight ounces of peroxid of hydrogen was poured into the cavity and then the peritoneum was flushed out with a saline solution. Finally, after being left full of the solution it was closed. The patient recovered.

DR. THOMAS B. SCULLY of Oneida County followed with a paper, entitled

APPENDICITIS: ITS TREATMENT FROM A MEDICAL AND SURGICAL STANDPOINT.

Two much importance has been placed on the surgical aspects of appendicitis. This has led to a reaction in many minds, and among a great many of the profession, and especially among the laity, the present rage for operation is considered a fad. For the first twenty-four hours, at least, appendicitis is practically always a medical affection. Though it must be borne in mind always that it may at any moment become a surgical one. If when a case is first seen morphin and strychnin be given hypodermically and magnesium sulphate by the mouth,

with an injection perhaps of water and glycerin, the medical man may await results. If the temperature and pulse are high, aconite and veratrum viride may be used in order to bring them down. If there is no abatement of the symptoms after twenty-four hours operation should be advised. The magnesium sulphate is best taken in teaspoonful doses every half hour until there is free watery evacuation. Salines used in this way deplete the inflammation, lessen the amount of toxins in the circulation, clean out the intestines and prepare the patient for operation later should it be necessary.

THE ADMINISTRATION OF NITROUS OXID WITH AIR OR WITH OXYGEN,

was the title of the next paper by Dr. Thomas L. Bennett of New York County.

He considers that nitrous oxid is the ideal anesthetic. It does not cause struggling or excitement and does not give rise to stimulation. Struggling at the beginning of an operation is often a serious matter. More than one appendicial abscess has been ruptured under such circumstances. For delicate patients excitement and stimulation are very exhausting. Then nitrous oxid does not cause disturbance of the heart, lungs, or kidneys. It has been given millions of times for the extraction of teeth, practically without ever causing death. It is especially indicated for very weak patients, or for those who from previous experience are known to stand the ordinary anesthetics, ether or chloroform, badly. It is also indicated for patients who have kidney or lung trouble or for the aged whose heart and lungs and kidneys are liable to be affected, and whose vascular apparatus is in a degenerated condition. The administration of nitrous oxid requires special experience, at least one death has been reported recently where a young interne in a hospital was administering gas and did not recognize the symptoms which indicated that the patient had had enough of the anesthetic and that it was dangerous to give more. Gas is particularly useful for small operations, like the opening of abscesses, the curetting of bone or of sinuses or the curetting of internal organs or in general for operations that take but a few minutes.

Dr. Merrill Ricketts of Cincinnati, Ohio, read a paper with the title

CHOLANGIOSTOMY, WITH REPORT OF TWO SUCCESSFUL CASES.

He reported two cases in which he has made incisions through portions of the liver substance in order to get at gall-stones in the intrahepatic ducts, or in a very contracted gall-bladder. Hepatostomy for these concretions that form within the liver is a thoroughly feasible operation. It used to be thought that incision of liver substances caused uncontrollable bleeding, but the wound may be packed and hemorrhage is easily managed. In one of Dr. Ricketts' cases constriction of the gall-bladder caused that organ to retreat so much beneath the edge of the liver that it could not be reached through the ordinary incisions made over the region of its fundus. In this case an incision was made through the liver, the stone removed, and the wound packed. Pus and bile flowed for six weeks, a sinus finally remained, but this at length closed. In another case the occlusion of the cystic duct seemed to have been brought on by a tubercular process in the biliary passages. Operation was performed through the liver and an attempt made to do a complete hepatoduodenostomy. The attempt was unsuccessful, principally owing to the fact that the tubercular process continued its course. Death ensued after five months.

The next paper was read by Dr. Reginald H. Savre of New York County and was entitled

THE DIFFERENTIAL DIAGNOSIS BETWEEN CHRONIC JOINT DISEASE AND TRAUMATIC NEUROSIS.

Error is comparatively easy in the differentiation of these two affection, though it is usually thought not to be. Mistakes are made, not rarely even by men of large experience. It is especially because the history of the patient is defective and sufficiently careful inquiry is not made as to the details of the affection. Hysterical joints may be differentiated from inflamed joints by careful examination of the patient. The absence of inflammatory signs is of some importance. Usually the patient will permit motion in the joint which was at first said to be very painful if manipulations are first undertaken in a neighboring joint. And this gradually made to include the affected joint without attracting the patient's attention. Where the case is seen several times, pains may be complained of at different points on different occasions. The general appearance of neurotic patients is an important pathognomonic sign which may be recognized without much difficulty.

In general the following rules will help in the diagnosis: A joint neurosis is apt to follow injury at a much shorter interval than does actual joint disease. The general temperature of the patient is usually a little below normal in neurosis. In inflammation of the joint it is usually higher than normal. The local temperature, that is, that of the affected part, is lower in case of a neurosis, while it is high in disease of the joint. Muscular atrophy progresses more rapidly after nerve injury. True muscular atrophy is not present except in joint disease. It may be simulated, however, by the atrophy of inaction consequent upon a hysterical joint affection.

Afternoon Session.

The first paper was read by Dr. Leroy J. Brooks of Chenango County. It was a sequel to his paper on the same subject last year, and was entitled

SUBNORMAL TEMPERATURE.

He considers that the temperature is frequently of diagnostic significance at the beginning of obscure affections. He has found, for instance, that melancholia is nearly always preceded by subnormal temperatures for some time. Often this subnormal temperature seems to be due to a weak circulation, especially to a weak heart, which by supplying insufficient nutrition to the brain predisposes to melancholia. Subnormal temperatures occur very often before attacks of epilepsy. Apoplexy seems often to be immediately preceded by a lower temperature

than normal, and low temperature always develops immediately after the seizure.

Of course, it must be borne in mind that certain people have a low temperature even in health, and of this fact the doctor must have cognizance before hand, or he will attribute to it a significance that it has not. Toxemias, especially toxemias of intestinal origin, are prone to give subnormal temperatures.

They occur in all diathetic diseases. They follow severe burns, especially if extensive, and certain skin lesions such as scleroderma produce low temperature.

DR. A. A. HUBBELL of Erie County next read a paper, entitled

EYE COMPLICATIONS IN TYPHOID FEVER

which appears in this issue of the MEDICAL NEWS.

The next paper, entitled

THE EFFECTS OF CERTAIN OCCUPATIONS ON THE PHARYNX,

was read by DR. SEYMOUR OPPENHEIMER of New York. He said that occupation pharyngitis is a rather common affection. An example of it may be seen from a recent case. A laundress developed a granular pharyngitis with relaxed mucous membrane, sore throat, constant expectoration, and congestion of the pharyngeal tissues. Treatment failed to be of much benefit. She had never been troubled before she took up the occupation of laundress, which required her to live a good deal in heated air. As soon as she changed her occupation the pharyngitis readily yielded to treatment.

It is usually not the temperature of the air, however, but the dust and foreign particles it contains which causes it to be irritating to the pharynx. Industries involving the breathing of smoke, of acid fumes, are especially liable to set up this industrial pharyngitis. In a recent case, a solderer of metals, who had worked a good deal where acids were commonly employed, had a pharyngitis that was very obstinate to treatment. Whenever he stopped work for a while, however, it immediately began to improve.

Young persons are much more affected than adults, and it is wonderful how soon after the mill is shut down. As soon as work begins again the old affection returns. The furnaces in our modern houses, with their dry, warm air, cause swollen, erectile tissue in the nose. This limits the amount of space through which nasal breathing may take place, and so mouth-breathing is begun, and this practically always causes pharyngitis. The treatment for occupation pharyngitis is mainly the use of simple alkaline sprays. The indication, of course, is adapted to remove the cause if possible by a change of occupation.

The next paper was read by DR. Z. J. LUSK of Wyoming County. Its title was

THE TOPICAL APPLICATION OF IODOFORM IN THE TREATMENT OF TUBERCULAR PERITONITIS WITH CASES.

He has found that in hopeless cases of tubercular peritonitis inunctions with iodoform and vaselin often seem to be effective in controlling the progress of the disease and causing the resorption of morbid products. He reported altogether eleven cases in which applications of iodoform and vaselin, 1 to 5, produced excellent results. With this treatment he combines tonics and cod-liver oil.

The paper by DR. JOHN W. S. GOULEY of New York County, entitled "Notes on Catheterism, Catheters and Bougies," was read by title.

DR. THOMAS F. REILLY of New York County, then read a paper, entitled

AN EPIDEMIC OF INTERCOSTAL NEURALGIA.

During the spring he saw a series of fourteen cases, including his own, of an affection that began with an intercostal neuralgia and was frequently complicated by an herpetic eruption. As other physicians in the neighborhood also saw cases of similar character he thinks he is justified in speaking of it as an epidemic. The first symptom was usually a severe pain in the left hypochrondriac region. This was continuous and the sensation was as if the spleen were pushing out the rib. After this there was profuse perspiration, then diminution of pain, and a drop in the temperature. The next day there was usually another paroxysm, repeating the features of the day before. After this the herpetic eruption appeared. In one case there were four paroxysms. There was no enlargement of the spleen in any case. In four of the cases the herpetic eruption occurred as herpes zoster or zona. In eight of the cases the herpetic vesicles appeared on the face, or on the mucous membrane. In two further case there was no eruption. There was a general pruritus which was not limited to the nerve over which the pain had occurred.

A number of things point to the fact that such cases are due to a special infectious agent that has its point of attack in the superficial nerve. One attack of the disease seems to confer immunity. There is a certain epidemic character about it, and in this series of cases three patients were members of one family, while in two other houses two members of the respective families were attacked. Epidemics of the disease have been reported from Vienna as occurring especially in the spring and fall. Sometimes the plasmodium malariæ has been found in the blood, but quinin had no effect in Dr. Reilly's cases. The best treatment seemed to be the strapping of the affected side with adhesive plaster. This should not be applied in a single piece as is often done, but in strips or ribbons about two inches wide.

The next paper, "Non-malignant Strictures of the Esophagus, Their Treatment by Retrograde Dilatation," by DR. HENRY MANN SILVER of New York County, was read by title.

DR. FRANK S. MILBURY of Kings County then read a paper, entitled

SUPPURATIVE ETHMOIDITIS AND ITS TREATMENT.

The ethmoidal sinus is the most frequently affected of the accessory sinuses of the nose. While suppuration is frequent, necrosis is rare. When suppuration occurs, eye symptoms frequently develop. There is pain at the base of the nose, or below the orbit, or back of the eye, or a painful sense of pressure over the whole head. Often

enough there is no pain at all. Sometimes there is a bulging at the inner canthus of the eye. Sometimes the tumor here ruptures and gives exit to pus. Usually pus will be found flowing from below the middle turbinated bone. Though the pus has a very unpleasant odor this is often not noticed by the patient himself, as the nerve of smell has been injured by the pathological process in the nose.

The indication in suppurative ethmoiditis is to provide a free issue for the pus. This should be done through the nose. In a number of cases the forceps invented by Dr. Milbury himself enable one to make a free opening into the ethmoidal cells in order to secure thorough drainage. It is not necessary then to remove very much of the middle turbinated, and the tissues of the nose with their important functions are spared.

The paper of DR. EDWARD H. SQUIBB of Kings County, entitled "Brief Comments on the Materia Medica, Pharmacy, and Therapeutics of the Year Ending October 1, 1899," was read by title.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 3, 1899.

THE President, FREDERICK PETERSON, M.D., in the Chair.

CEREBELLAR TUMOR.

DR. W. B. NOYES presented a boy, aged five years, who had been well up to last June. At that time he had had an obscure illness which had been diagnosed by the attending physician as an auto-intoxication. He had remained unconscious for two days. During July he had been in fair condition. In August it was noticed that he staggered when walking. When sitting down he could move his legs, but there was absolute ataxia. There was a slight spastic condition of the legs which interfered with properly obtaining the knee-jerk. Ankle clonus could be occasionally elicited. There were no sensory disturbances of any sort. His mental condition was becoming slowly worse. Examination of the eyes showed papillitis with hemorrhages over the disk. The pupils were dilated and did not respond to light. There had been neither headache nor vomiting. The case was presented as probably one of cerebellar tumor. The speaker said that it was not impossible that the sickness which had occurred last June might have been a meningitis; it was also possible that there was a hydrocephalus.

DR. GEORGE W. JACOBY said that he had been impressed with the general laxness of the boy and the bending forward of the thorax. This general loss of muscular tone made him believe the diagnosis of cerebellar tumor to be correct.

DR. HUGHES of St. Louis said that while the case suggested cerebellar tumor it seemed to him not improbable that there had been a cerebrospinal meningitis, and that the present condition was the result of this meningitis.

DR. EDWARD D. FISHER inclined to the view that the case was one of cerebellar tumor, although admitting the force of the statement of the last speaker.

DR. NOYES thought the condition of the eyes alone seemed competent to settle the question of the diagnosis. He had been unable to find the report of a case of hydrocephalus producing optic neuritus, although it might cause optic atrophy when very far advanced. The disease was evidently progressing rather rapidly now.

BRACHIAL PLEXUS PRESSURE PARALYSIS.

DR. WILLIAM M. LESZYNSKY presented a young woman having a brachial plexus paralysis affecting both arms, the result of pressure. The biceps group was paralyzed; the extensors and the deltoid were extremely weak; there was an atrophy around the shoulder joint. There were no sensory symptoms. The faradic irritability was lost in the nerves and muscles. On the right side there was the same condition, although to a less degree. The paralysis had existed three months. The etiology in this case was interesting. She had been operated upon about three months ago for an abdominal growth. Immediately afterward a paralysis had developed, undoubtedly from the pressure exerted for about one hour and a half by an apparatus used for support. Dr. Leszynsky said he had seen similar cases of pressure paralysis, but in this instance the paralysis had been so severe, and had lasted so long that it brought up the interesting question as to whether or not the surgeon might not be open to a suit for damages. On inquiry he had learned that this form of paralysis was not at all uncommon at the present time in surgical practice, yet it was entirely avoidable. In an article by Dr. Garrigues several cases had been reported in which the paralysis had lasted for a year or more, and had been followed by atrophy. The apparatus referred to usually made pressure between the clavicle and the first rib.

DR. FISHER said that these cases of pressure paralysis were quite commonly observed after operations, as for example for appendicitis, but he had never before seen a case in which both sides had been involved. Negligence in attending to the position of the arm during operation was often responsible for such paralysis.

DR. FRAENKEL said that while many cases of post-operative paralysis had been reported, it should be remembered that in some the paralysis had been ascribed to the ether, although in others the influence of pressure had been definitely shown. This made it difficult to hold the surgeon liable in many instances.

DR. G. W. JACOBY said that the various cases had been recently tabulated and the conclusion reached that all the paralyses could only be explained by pressure. The concensus of opinion at the present time seemed to be that the ether could not give rise to this form of paralysis. Surgical assistants were often very negligent about these matters. For example, he had found an assistant giving hypodermic injections of ether and brandy in a case of collapse, directly over the musculospiral nerve, and the ensuing paralysis he would have found difficulty in explaining had he not seen these injections being given. Again, he had known it to be positively asserted that there had been no pressure, and yet he had personally seen the etherizer resting his elbows heavily over the patient's clavicles.

Dr. Frederick Peterson said that he had seen even the peroneal nerve affected in this way after ether narcosis. In every case that he had investigated he had found that there had been a possibility of the paralysis having been produced by pressure. The question was of great importance, for he believed it would be perfectly possible for such a paralyzed patient to collect damages from the surgeon on account of such negligence. Nearly all the pressure paralyses occurring at night developed during alcoholic sleep, and he had come to look upon these as occurring in nerves which had been rendered especially vulnerable by ether or alcohol, or, as suggested by Dr. G. W. Jacoby, the inhalation of carbonic oxid in close sleeping-rooms. In cases of musculospiral palsy the nerve was generally pressed upon when the patient slept with the arm raised and the hand under the back of the head.

Dr. Hughes said that the paralyses following the comatose state in epilepsy exhibited local peripheral expressions. Neurologists had been accustomed to consider these as of central origin. His own opinion was that ether was a factor which could not be ignored—that it was a toxic factor, acting on the peripheral cells, thus rendering the nervous system vulnerable, just as did alcohol. He had not yet been convinced that these cases were exclusively peripheral paralyses, and owing to this lack of unanimity among neurologists regarding the causation of these cases their medico-legal aspect assumed grave importance. Many of these patients recover just as in the case of epileptic paralyses, and he was inclined to think that the toxic condition of the brain found associated with etherization was an important etiologic factor.

Dr. Leszynsky said that he could not agree with the views of the previous speaker regarding the effect of etherization. When a healthy person was etherized it could hardly be said that the toxic condition was so soon responsible for the paralysis; it was rather a case of extreme pressure made during unconsciousness. In his own mind there was no question that all of these cases were directly due to pressure made during unconsciousness. Ether, like other stimulants, might give rise to cerebral hemorrhage, or induce hemiplegia of the hysterical type. If these cases were due to a lesion in the anterior horn they would not all recover, as occurred invariably in the class of cases under discussion.

THE CENTRAL NERVOUS SYSTEM IN ACUTE MALARIAL INFECTION.

Dr James Ewing read this paper. He introduced the subject by reporting the following three cases:

Case I.—Estivo-autumnal malaria, with marked cerebral symptoms and infection with a single, well-defined group of parasites. The patient was a soldier who had just returned from Cuba. The stupor lasted thirty-six hours prior to death. Two days before death there had been many ring-shaped organisms in the blood. The stupor began twelve hours after sporulation occurred. At the autopsy the viscera showed the lesions of severe malarial infection. The capillaries of the cerebrum, cerebellum, medulla, and cervical cord contained a large number of cells harboring parasites. Many capillaries were occluded by thrombi. The ganglion cells showed everywhere a reduction in size, irregularity and splitting or loss of the chromatic bodies. Death was due to the massing of the parasites in the capillaries. The case was a good example of comatose malaria of the cerebral type.

Case II.—This patient had chills on alternate days for several days, and on admission had a pulse of 110, and was much prostrated. There were marked insomnia and mild delirium for awhile; then the delirium became more marked, and finally there was coma, lasting for some time before death. There was no evidence that the coma was uremic. The temperature reached 108° F. shortly before death. On October 12th the blood contained an enormous number of ovoidal, spherical, and crescentic bodies. On October 25th, or eight hours before death, very few crescents could be seen. None of the younger forms was found. The autopsy showed moderate edema of the brain, the basal vessels normal, and very few parasites present. The deposit of pigment in the brain was slight. Throughout the cortex the cells showed no marked change further than a uniform diminution in the chromatic substance. In many of the pericellular lymphocytes were peculiar structures—elongated fibers or rods with tapering ends—of undetermined nature. Similar deposits were found in other cases of malaria, and in one case of tubercular meningitis. The chief feature of this case was the prolonged delirium and coma, yet the post-mortem examination showed far less change in the kidney than was usually seen in profound malarial infection.

Case III.—This was a case of fatal malaria associated with hemoglobinuria. The man had contracted malaria in Santiago in July, 1898. He was comatose, extremely emaciated, excessively anemic, and moderately jaundiced. He was at Camp Wikoff for three days prior to death. The dura and pia were distinctly jaundiced. The cerebrum, cerebellum, and medulla showed the usual injection of vessels with blood, but the vast majority of the vessels were free from the parasites. An abundant deposit of hematoidin in the kidneys was interesting.

Commenting upon the foregoing cases, the speaker said that when the brain cortex was markedly brownish it indicated usually the presence of a large number of parasites, but this was not an invariable rule. The majority of cases of comatose malaria did not exhibit the massing of the parasites in the brain. Of eight cases in which he had examined the brain after death in none was there a distinct brownish discoloration of the brain. Hemorrhages had been found in some cases, as had also a moderate degree of edema. Usually the parasites were uniformly distributed in the brain and cord, but a case had been reported in which they had been localized in the medulla. The number of these parasites was often enormous, and complete occlusion of the vessels was not at all uncommon. While most of the fixed pigment was found in the endothelium, the parasites were rarely seen in the endothelial cells. To the general condition of the obstructed circulation it was probably safe to refer the

cerebral symptoms observed in these severe cases of malarial infection. The ganglion cells, in cases of comatose malaria, had been studied, and the changes found to consist chiefly in the various degrees of chromatolysis. The dendrites were usually involved before the cell body. The ganglion cells appeared to suffer less than in the average case of typhoid fever. The mere presence of the parasites in the tissues seemed to exert no bad influence except in a mechanical way. In one of the cases reported in the paper the deepening of the coma could be apparently connected with the progressive filling of the capillaries with the parasites and the formation of thrombi. In the other two cases the parasites were few and the pigment scanty. In both of these cases the malarial infection was exceedingly severe. These cases showed that the coma of malaria was not always referable to the presence of the cerebral parasites. Of the writer's sixty-four reported cases of malarial coma, there were five simple tertian infections. In the estivo-autumnal cases, with crescents only in the blood, there were thirty-four instances from the Montauk camp. Coma appeared to be rather frequent in patients showing only crescents in the blood. Crescents did not exhibit such a tendency to unequal distribution as did the fertile forms. From the condition of the viscera found in the second and third cases reported—and this variety occurred expecially in cachectic individuals in whom the disease had existed for some weeks—it seems probable that the coma was the result of the general and profound malarial infection. The writer did not believe that much importance should be attached at the present time to the condition of the ganglion cells in malaria. When the coma resulted from the massing of the young parasites in the brain, it was generally gradual in onset, and the prognosis was very unfavorable. In some cases the coma developed suddenly, and was more amenable to appropriate treatment. The general clinical character of these cases indicated that an embolic process was concerned in their causation. Of eleven cases of the first class, reported by the writer, ten proved fatal. To summarize: The three anatomical conditions were: (1) The mechanical obstruction of the cerebral capillaries by large numbers of young parasites; (2) an embolic process causing an occlusion of some vessels (usually temporary) by parasites or pigmented leucocytes, and (3) a general toxemia, such as might occur in other infectious diseases, the blood showing few, if any, autumnal rings.

DR. W. B. NOYES said that two years ago he had seen at the Columbus Hospital, in the service of Dr. C. H. Lewis, a case in which there was coma, stertorous respiration, partial paralysis and irresponsive pupils. The blood taken from the spleen at autopsy showed the presence of pigmented leucocytes, parasites of the estivo-autumnal variety. Sections from every part of the brain, without staining, showed that the walls of the capillaries were infiltrated with pigment. The absence of the parasites and the enormous amount of pigment were especially noteworthy. In the other organs of the body the usual lesions of pernicious malarial fever were found. In this case the diagnosis during life had been cerebral hemorrhage by almost every physician who had seen the case—certainly the clinical appearances were the usual ones found in cerebral hemorrhage.

DR. LEWIS A. CONNER thought the jaundice might explain some of the comas that were otherwise inexplicable. It was surprising sometimes how an apparently moderate degree of jaundice might be associated with very marked cerebral symptoms.

DR. FRAENKEL said that he looked upon most of the nervous consequences of malaria as due to toxemia. He was reminded of a patient who had presented a well-defined picture of aneurism at the base of the brain. He had been under observation for a considerable time without noteworthy symptoms until suddenly he had chills and fever. At that time the patient was in a room in the hospital in which there had been malarial fever. The chills and fever recurred regularly for two or three days, and then he was removed to another room. He then had an acute maniacal seizure, and after half an hour talked in a typical paranoiac fashion. He next became rational, but developed the same train of symptoms the next day at the same time. The blood showed the estivo-autumnal parasites. The man finally recovered, and is well at the present time. Another case was cited bearing upon the view that a malarial toxemia was responsible for most of the nervous symptoms. When first seen this person had been sick only two hours. He stated that he had suddenly become unconscious, and that this had been immediately followed by a urticarial eruption. He had a very slow pulse and some fever. On the third day there was a severe chill, some jaundice, and a temperature of 104° F. The blood showed the presence of the parasites of estivo-autumnal malaria. The patient recovered in due time, only to have a similar attack about the same time the following year. Such a case, the speaker thought, could hardly be explained by mechanical obstruction; it was rather an example of the effect of a general toxemia.

DR. HUGHES said that the paper was very satisfactory in that it explained certain old and well known clinical facts. Williamson of England had been one of the first authors to refer to the effect of malaria on the nervous system. A case of infantile paraplegia was recalled which he had seen many years ago. When first seen the patient had been unable to sit or stand. He had at once suspected malaria, and a vigorous course of quinin had resulted in a rapid and seemingly miraculous cure. He was inclined to believe that the effect of malarial infection was principally spent upon the vasomotor system.

DR. WILLIAM HIRSCH reported a case of a gentleman sent to him from the South about one year ago, with a diagnosis of spinal tumor. The symptoms were atrophy of the muscles of the left shoulder, associated with intense pain. The patellar reflexes were exaggerated. After having had the patient under observation for some time, and studying the previous history very carefully, he had become convinced that this was not the correct diagnosis. The patient gave a history of having had a somewhat similar attack some time before from which he had recovered. While under observation the

man had developed a typical malarial temperature, and this had been associated with splenic enlargement. Examination of the blood at that time had been negative. After about six weeks of antimalarial treatment recovery had been complete. A very peculiar symptom in this case was a decidedly tender swelling over the sternum. This had disappeared as the patient had improved. The man, against advice, had returned to his home in the South, and when seen again, a few weeks ago, had been in a worse condition than the year previous. The left clavicle then exhibited a tender swelling, like that observed previously over the sternum. There were similar swellings over one ulna and on one portion of the skull. He was now improving rapidly under antimalarial treatment. The case was reported because of this peculiar affection of the bones.

DR. TELLER of Memphis said that he practised in a district in which malaria was exceedingly common and very malignant. In his neighborhood these peculiar neurotic manifestations of malaria were so common as to make the physicians constantly on the lookout for them. The cases of cerebral congestion were all too common, and very frequently proved fatal. The physicians of his locality looked upon the disease as a profound toxemia.

DR. EWING said that he had been especially interested in the remarks of one of the speakers concerning patients exhibiting jaundice. These subjects commonly showed at autopsy profound and peculiar changes in the liver. In the cases reported by Dr. Hirsch there were certain features that seemed to him to point to syphilitic infection. In conclusion, the speaker said that the medical profession is too prone to jump to the conclusion that a disease is malarial because it seems to respond to the administration of quinin. A very large number of nervous conditions, that had been referred to as malaria by the older writers, should be excluded at the present time, because they had not been properly authenticated according to modern notions.

THERAPEUTIC HINTS.

For the Induration of Eczema and Psoriasis.—UNNA of Hamburg states that the induration observed at the site of old spots of eczema or psoriasis are not due to an infiltration of the corium, as is generally believed, but to a simple hyperplasia of the Malpighian layer of the epidermis, which he treats as follows: If the affected areas be limited in extent:

℞ Ungt. zinci oxidi, Resorcin aa. . . . ℥ ss
Ichthyol, Vaselini aa. . . . . ʒ i.
M. Ft. unguentum. Sig. External use.

If the areas be extensive the application should be less powerful:

℞ Ungt. zinci oxidi . . . . ℥ iss
Resorcin, Vaselini aa. . . . . ℥ ss.
M. Ft. unguentum. Sig. External use.

A thin layer of the ointment is spread over the indurated areas daily until the epidermis begins to peel off, which occurs in from one to three days. The applications then cease, and if the process be painful a sedative ointment is used until the new epidermis is formed.

For Painful Bruises.—

℞ Tinct. aconiti, Tinct. opii, Chloroformi aa. . . . . ℥ ss.
M. Sig. External use. Shake well.—*Whelpley.*

Liniment for Use in Rheumatism.—

℞ Tinct. camphoræ, Tinct. opii, Spts. ammoniæ aa. . . . ℥ ss
Ol. olivæ . . . . . ʒ i.
M. Ft. emulsio. Sig. External use.—*Dunglison.*

For Sensitive and Irritated Nipples.—

℞ Ichthyol . . . . . ʒ ii
Lanolini, Glycerini aa. . . . . ʒ iiss
Ol. olivæ . . . . . ʒ v.
M. Ft. unguentum. Sig. External use.—*Oehren.*

The Usefulness of Spartein in Cocain Anesthesia.—SCHEPPEGRELL claims that danger of heart failure from cocain is avoided by the simultaneous employment of spartein which acts as a cardiac tonic while not detracting from the anesthetic effect of the cocain. Three-quarters of a grain of spartein allowed to three-fifth of a grain of cocain.

To Promote Uterine Contractions.—In cases of deficient contractions during labor, due to a lack of muscle tone, the following formula is recommended:

℞ Quininæ sulphat. . . . gr. xl
Ac. sulphur. aromat. . . . q. s. ft. sol.
Syr. zingiberis . . . . ʒ i
Aquæ . . . . q. s. ad. ʒ ii.
M. Sig. Initial dose, one tablespoonful; afterward, two teaspoonfuls every four hours.—*Ringer.*

For Bronchitis.—

℞ Syr. tolutani, Syr. pruni virg., Tinct. hyoscyami, Spts etheris comp. aa. . . ʒ iii
Aquæ dest. . . . q. s. ad. ℥ ii.
M. Sig. One teaspoonful every three hours.—*Janeway.*

For Syphilitic Alopecia.—It is advisable to keep the hair cut short and to frequently apply a stimulating lotion, such as the following:

℞ Hydrargyri chloridi corros. . . gr. iv
Chloralis hydrat. . . . ʒ i
Resorcin . . . . ʒ ss
Ol. ricini . . . . *m.* xvi
Tinct. cinchonæ . . . ℥ ii
Spiritus (ninety per cent.) . . ℥ v.
M. Sig. Apply to scalp.

The patient should be told that temporary reddening of the hair may result from the use of the cinchona.—*Gaucher.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, NOVEMBER 18, 1899. NO. 21.

ORIGINAL ARTICLES.

THE TREATMENT OF GONORRHEA IN THE FEMALE.[1]

BY A. RAVOGLI, M.D.,

OF CINCINNATI, OHIO.

GONORRHEA in the female is as interesting a disease in the sexual sphere as it is in man. It often causes serious complications which may expose the life of the woman to grave danger. It is the result of the local infection by the gonococci, which are constantly present in every case. Indeed, I never wish to establish the diagnosis of gonorrhea if I do not find the cocci in the secretion. The microscopical examination of the secretion is so easily and so quickly made that I consider it to be great negligence on the part of a practitioner to diagnose gonorrhea without an examination of the discharge.

On account of the anatomical disposition of the organs in woman, gonorrhea always becomes more complicated, and one must distinguish the affection according to the parts affected. As in man the disease affects the urinary and generative organs, and on account of their vicinity, both are often infected. As a result, there may be a urethritis, cystitis, vulvitis, bartholinitis, vaginitis, cervicitis, endocervicitis, endometritis, and as a consequence salpingitis, oophoritis, and peritonitis.

As in man, in woman also, gonorrhea may be acute or chronic. I will not dwell long on the acute cases which present symptoms so severe and so marked as to compel the woman to seek relief from the medical profession. In these cases an abundant purulent discharge of an offensive odor oozes from the vulva, which, on account of its irritating qualities, causes intertrigo of the surrounding skin of the thighs and of the labia, with a burning and itching sensation. The labia minora are red and swollen, and if the Bartholinian glands are affected there is great swelling of the labia majora posteriorly, with pain spreading down to the thighs and to the knees. In these cases the urethra is also affected. The patient cannot retain her urine. She has tenesmus and sometimes cystitis. The suffering from acute gonorrhea is such that the woman will remember it for a long time, and will refer to it as one of the most important points of the anamnesis.

In most of the cases we have to do with chronic gonorrhea which is the result of an acute attack. Gonorrhea often remains concealed in the female genital organs without producing troublesome symptoms. I have often heard women affected with chronic gonorrhea deny any suffering, complaining only of what they call female trouble, whites, or leucorrhea. Julien has very happily described the troubles of a woman affected with chronic gonorrhea. It is not infrequently found in married women who have been infected by their husbands, who at the time of marriage still had some trace of an old posterior gonorrheal urethritis, which had been thought entirely innocent and of no consequence whatever. As the sufferings have begun after the wedding trip this is looked upon as the origin of all the trouble.

In acute cases when the discharge is so abundant that it soils every part it is impossible to distinguish the organs which have been affected and the organs which have been spared. In the subacute or chronic cases, and especially when the infection has been produced by an old, latent case of gonorrheal urethritis, one can see the organs affected and establish the exact diagnosis. I will introduce a few statistical tables taken from my hospital practice from September, 1894, to September, 1899, five years:

	Acute gonorrhea.	Chronic gonorrhea. Urethritis.	Vaginitis.	Cervicitis.
1894	51	3	1	
1895	117	6	5	2
1896	113	4	3	
1897	112	2	2	4
1898	50	6	3	1
1899	29	4	3	

	Bartholinitis. Acute with abscess.	Chronic catarrh of the excretory ducts.
1894	0	5
1895	2	7
1896	0	6
1897	1	4
1898	2	6
1899	0	3

	Subacute and chronic gonorrhea. Endocervicitis.	Endometritis.
1894	5	24
1895	10	28
1896	7	30
1897	8	46
1898	12	52
1899	6	16

[1] Read at the Annual Meeting of the Mississippi Valley Medical Association, held at Chicago, Ill., October 3–6, 1899.

	Complications of the uterine adnexa.	
	Pyosalpinx.	Oophoritis.
1894.....	0	3
1895.....	2	
1896.....	19	
1897.....	20	
1898.....	14	
1899.....	11	3

The disproportion between the acute cases of gonorrhea in reference to the chronic cases is due to the gravity of the symptoms in the first and to the mildness of the same in the second. I must remark, also, that the large number of cases in the years 1895, 1896 and 1897 was due to the enforcement of police regulations. In these three years the houses of prostitution were frequently raided, the inmates were taken to the hospital and subjected to examination, and if found diseased were detained in the institution.

In woman, as in man, Nature has placed some obstacles to the progress of the gonococci so that when a contiguous organ is recently attacked we find it to be a new complication, although it is nothing more than the spreading of the same process. When the infection originates from a chronic gonorrheal urethritis in the man the organs of the woman which are more exposed to the contagium are the urethra and the cervical canal. Indeed, in the majority of these cases we often find a subacute and chronic urethritis combined with endocervicitis. The vagina is seldom affected in adult life, and my statistical table shows only a few cases. The infrequency of gonorrheal vaginitis in adults caused its possibility to be denied, but after awhile it was established by the observations of Mandl[1], Doederleins, and Bumm[2], and thoroughly described by Calmann[3] from his observations in the clinics of Dr. R. Asch.

An acute vulvovaginitis is often found in children, when either by criminal act or by accident they become infected with gonorrheal virus. The resistance of the epithelium of the vagina in the adult I believe to be a great safeguard against the action of the gonococci. My cases of vaginitis and cervicitis have occurred in very young women, very weak and anemic and previously affected with leucorrhea. The leucorrhea macerating the epithelium of the vagina has been the cause of preparing the ground for the proliferation of the gonococci, which in the normal condition would probably have found an obstacle to their proliferation in the resistance of the epithelium of the vagina and of the cervix.

The organ which comes in contact with the meatus of the male urethra in the act of coitus is the cervix. It is furnished with a thin and delicate cylindric vibratile epithelium and the gonococcus finds there a good ground for its development. When the cervical canal is so affected, although it is an integral part of the uterus, the condition is not a true endometritis. The os uteri internum, which divides the cavity of the cervix from the cavity of the uterus, is a boundary which prevents the gonococci from proceeding further and infecting the endometrium. It is for this reason that so many cases of endocervicitis occur while endometritis is comparatively rare. When the gonorrheal affection spreads to the body of the uterus in an acute form the woman is seized with a chill, fever, general malaise, and pain in the abdomen, which is tender and cannot bear any contact. An abundant mucopurulent discharge flows from the cervix into the vagina which soils the linen and inflames and excoriates the skin. At times the woman suffers from irregular hemorrhages, and the menstruation becomes irregular, prolonged and very profuse.

In the chronic gonorrheal endocervicitis the process which for some time has remained latent in the cervix spreads to the endometrium without causing acute symptoms. The woman does not perceive any other apparent sign than a kind of moisture of the genitals. Subjective symptoms are gradual in their occurrence. The menstruation is preceded and accompanied by pains which before were never present; the period is disturbed, sometimes advanced, at other times retarded. She complains of backache, which she attributes to a strain, having lifted a heavy bucket, etc. She feels bearing-down pains in the abdomen which spread to the internal region of the thighs. She loses her appetite, her digestion is impaired, and a constant sense of fulness prevents her from eating. In a great many cases constipation increases her troubles, and in others micturition is frequent. Her general health begins to suffer. She becomes anemic, loses sleep, and diminishes in weight. She gradually becomes a neurasthenic, is extremely sensitive to all impressions, and everything affects her mentally. Sympathetic pains are felt on one or both sides of the abdomen, showing complications on the part of the tubes and ovaries. Often a woman in this condition coming to a physician does not believe that the condition of the uterus is the real cause of all her sufferings and refuses an examination. It is therefore our duty to insist upon an examination and ascertain the condition of the womb.

The examination of these chronic cases usually does not reveal much of an alteration of the external organs, with the exception of a slight redness of the ostium vaginæ. Introducing the speculum a scanty mucous discharge is found oozing from the os

[1] *Monats. f. Geb. und Gyn.*, Heft 1, 1897.
[2] Veit, "Handb. d. Gyn.," Bd. I., p. 474.
[3] *Derm. Zeits.*, Heft 4, August, 1899.

uteri, which is sometimes yellow, of a crystalline appearance, sometimes whitish, thick, tenacious and adherent. The mucus is removed with difficulty by washing with a stream of antiseptic solution. It can only be taken away by wiping with a piece of dry cotton. Often around the cervix are abrasions and excoriations which bleed at the slightest touch. The lips of the cervix appear deeply red, excoriated, covered with small granulations and in ectropic condition. I introduce a small tampon of cotton fastened about a thin uterine sound into the cervix as far as possible in order to take the mucus off the cervix, and with this I smear glass slides to search for the gonococci.

So far one can only establish the existence of an endocervicitis, but is still in the dark about the condition of the endometrium. Chronic gonorrheal endometritis we have reason to suspect already from the persistence of backache, the heavy feeling in the hypogastrium, and by reason of the disturbances of the menstrual periods. The physician will acquire the certainty when, on introducing his finger into the vagina and pressing down with the other hand on the hypogastrium, he finds the uterus very tender to pressure, hard, swollen, and increased in size. Although the introduction of the uterine sound would give the exact measure of its cavity, it is better to avoid this procedure for diagnostic purposes, because this is frequently the means of spreading the infection from the cervical canal to the endometrium. Gonorrheal infection does not limit itself to the cavity of the uterus, but may spread from it to the tubes, to the ovaries, and to the peritoneum, causing dangerous complications. Gonorrheal infection may also be carried by the circulation to the serous membranes of the body, causing gonorrheal rheumatism. In four cases of gonorrheal arthritis I could confirm the observations of Finger and others, demonstrating large quantities of gonococci in the pus and in the serum of the joints.

Returning to our subject of treatment, gonorrhea in the female as in the male must be treated in the locality where it has developed. The object of the treatment is to remove promptly and often the secretion from the mucous membranes and destroy the gonococci in the locality. The first aim is obtained by repeated and prolonged irrigations with antiseptic solutions; the second, by applications of remedies capable of causing a superficial necrosis of the epithelium, thereby reaching the gonococci which enter into the epithelial cells and find their way to the subepithelial layers of the mucous membrane. In regard to the first method, irrigations are made with solutions of bichlorid of mercury, 1 to 5000, or with permanganate of potassium, 1 to 5000. These irrigations are easily applied to the external genitalia, to the vagina, and to the vaginal portion of the cervix. With an ordinary fountain-syringe the woman can herself take the douches with one of these solutions twice a day. These will remove the mucopurulent secretion, will diminish the inflammation, but of course will not help the urethra nor the condition of the uterus. Every two or three days I insert a bivalve speculum, and with a solution of permanganate of potassium, 1 to 5000, thoroughly irrigate the vagina; then with small tampons of cotton the secretion from the cervix is carefully removed. When abundant discharge is flowing from the cervical canal I insert a Talley or Haynes douche-tube into the cervix as far as the internal os, and with a mild stream of the same solution the cervical canal is washed. When symptoms of urethritis are present the urethra is also irrigated with the same permanganate solution. This is also done by means of a short recurrent catheter. I do not find it useful to fill up the female bladder as in the male by the Janet method. The sphincter of the bladder in the female offers a great resistance to the passage of the fluid, and a forced injection into the urethra is accompanied by pain. The fluid is carried into the bladder only with difficulty. For this reason I prefer to introduce a recurrent catheter any time I have to irrigate the female urethra and the bladder. Under ordinary circumstances I seldom make use of irrigation to the cavity of the uterus unless the discharge is very profuse. Ordinarily I use instillations with a one-per-cent. solution of protargol.

The most effective antigonorrheal remedies so far known are ichthyol and the silver preparations. Ichthyol has a beneficial action, especially in cases of acute gonorrhea in the female, and in my clinics every case of acute vaginitis and vulvitis easily yields to a few applications of tampons dipped in a preparation of ichthyol and glycerin, equal parts. In the subacute and chronic cases, however, the silver preparations are much more desirable. Nitrate of silver in substance, in a thin, flexible rod, so much used in past years to cauterize the cervical canal, has been nearly discarded in ordinary cases. I reserve this cauterization for cases in which granulations are to be destroyed. In the same way I use strong solutions of the same salt only when the cervix shows excoriations with granulations. Protargol I have found so far to be the best antigonorrheal remedy, and since the time I introduced it in my clinic I have many times spared the patient a curettement of the uterus. Protargol has been used in from one- to three-per-cent. solution as a urethral injection in cases of urethritis, as an injection into the ducts of the Bartholinian glands when

affected, and especially in endocervicitis and endometritis. One of the instruments already referred to, the Talley or the Haynes double tube, has been introduced very gently into the cavity of the womb, care being taken to fill the tube with the fluid before introduction, otherwise some air is carried into the cavity. The instrument being in place, the fluid is pushed out of the syringe very slowly, drop by drop. I leave the catheter in for a short time so as to give the fluid a chance to flow back. Without this precaution, if some of the fluid remains in the body of the uterus, the woman may suffer from cramps and uterine colic. After removing the catheter a tampon is introduced to maintain the fluid in contact with the cervix.

The instillation of protargol into the uterus causes only a sense of heat in the hypogastrium, which lasts about half an hour. From this treatment the results have been exceedingly gratifying. Five to ten applications have been sufficient to bring the womb to its normal condition. Protargol in the beginning increases the discharge, which gradually diminishes, and is reduced to a thin crystalline mucus. As soon as the gonoccoci have disappeared from the secretion the instillations with protargol are discontinued, and the woman uses douches of a mild solution of permanganate of potassium or of biborate of sodium.

So far I cannot agree with Calmann on the superiority of formalin in this treatment, and I find that protargol is safer and more effective in subacute and chronic cases of gonorrheal endometritis. During treatment it is of great importance to watch the menstrual periods. While the woman improves, her menses return to the normal condition, and the accompanying pains gradually disappear, yet after the menstruation some mucus secretion passes from the uterus. This secretion must be carefully examined for the gonococci. If gonorrheal germs still remain in the glands or in the folds of the mucous membrane of the uterus, with the presence of the blood, with the menstrual hyperemia, it seems that they take on more vitality, and are to be found again in the mucus. For this reason, before discharging a patient as cured, it is best to wait until her menstrual period occurs, and then to examine the secretion.

I must add a few remarks on the curettement of the uterus in chronic gonorrheal endometritis, which has been resorted to as the only and last treatment. This operation should not be performed in cases in which the inflammatory process is still active. It increases the inflammation, and often is the cause of the spreading of the gonorrheal process to the tubes and ovaries. In chronic cases for several years I have found curettement to be the only remedy for chronic gonorrheal endometritis. From my hospital records I find that in 1895 I curetted in 14 cases, in 1896 in 30 cases, and in 1897 in 50 cases. After I began to use the treatment of instillation of protargol in 1898, I curetted in 6 cases, and in 1899 to the present month, only in 2 cases. This shows clearly the beneficial effect of this treatment, and I am gratified o state that in our ward in the last two years no complications have arisen in connection with the tubes, the ovaries or the peritoneum. During the treatment one must not forget the general condition of the woman. Constipation is often present, and for this I advise her to take half a glass of a mild purgative mineral water, with preference for apenta, which corresponds very well to the indication. At the same time the hypohemic condition must be altered by the administration of a mild ferruginous preparation.

Before concluding I must remind you that gonorrhea sometimes complicates pregnancy and the puerperium. Acute gonorrhea affecting the endometrium of the pregnant uterus is the cause of abortion. In chronic cases, however, pregnancy progresses without any trouble. In these cases the woman will irrigate the vagina with a mild solution of permanganate at a pleasant temperature, but the cervix and uterus cannot be treated directly with injections or with cauterizing agents, as they would without doubt cause miscarriage. At the same time rest should be recommended in order to spare the womb shocks, which might result dangerously. After childbirth chronic gonorrhea of the cervix may spread to the endometrium and cause subacute endometritis, which is accompanied by severe pain and a copious discharge of seropurulent secretion, which mixed with the lochia may give an idea of a septic condition. Differentiation, however, is easily made between gonorrheal endometritis and septic endometritis by the temperature curve, which in gonorrhea is mild or absent and in the septic endometritis is very high and by the odor of the lochia which in the gonorrheal condition have no offensive smell, but which in septic endometritis have a nauseous unbearable odor. It is unnecessary to say that a woman must be kept in bed in a state of absolute rest. Morphin must be administered to relieve the pain. Hot applications to the hypogastrium have a beneficial effect. Warm irrigations with antiseptic solutions to wash out the vagina and remove the secretions should be carried out. Stronger applications are reserved until after the puerperal period is over.

Gonorrhea is not difficult to cure when every af-

fected organ is treated. The trouble is in the possibility of reinfection. For this reason one should recommend, especially to a married couple, when both have suffered from gonorrhea, the use of a condom for a long time, until both are completely cured.

AN EXPERIMENTAL STUDY OF ASPIRIN, A NEW SALICYLIC-ACID PREPARATION.

By F. C. FLOECKINGER, M.D.,
OF LA GRANGE, TEXAS;
EX-SURGEON TO THE CITY HOSPITAL OF RIO DE JANEIRO, BRAZIL.

FOR some time I have been engaged in investigating a new preparation which is practically unknown in the United States, while only two reports of its properties have been published in Europe. One of these reports is from Dr. Julius Wohlgemuth, Assistant Physician at the Medical Clinic of Professor Leyden[1] of Berlin. The other is by Dr. Kurt Witthauer,[2] Physician and Chief of the Deaconess Hospital at Halle. No article in English has appeared upon this preparation up to the present time.

This new product, which has been introduced into the market under the commercial name of Aspirin, is a combination of acetic acid with salicylic acid. Acetyl salicylic acid (aspirin) is prepared by the action of acetic acid anhydrid upon salicylic acid. It occurs in the form of white crystallin needles, which have a melting-point of 135° C. (275° F.). Ortho-oxybenzoic acid (salicylic acid), which is found in nature as an aldehyd in the ethereal oil of the spiræa ulmaria, Linné, and other varieties of spiræa, as well as in the ethereal oil of gaultheria procumbens, Linné, has since the first experiments with it by Buss and Stricker, in 1876, proved an invaluable remedy in rheumatic conditions. As is generally known, this preparation, however, has the disadvantage of producing gastric disturbances, besides tinnitus aurium, delirium, depression of the heart, troublesome headache, and even conditions of collapse. The new product, aspirin, is soluble in weak alkalis, and as shown by experiments is separated into its two components in the course of three to five minutes. Hence, its action does not take place until it reaches the alkaline intestinal juice by which it is decomposed. In pathological conditions of the stomach in which acidity or subacidity prevails, as in carcinoma ventriculi, a partial decomposition of aspirin occurs in the stomach. In a case of advanced gastric cancer I administered for the purpose of experiment 1 gm. (15 grains) aspirin three times daily. The gastric juice was withdrawn one hour after its administration and tested, with the result that a reaction was obtained by means of iron chlorid solution, showing that free salicylic acid was present in the stomach. On the second day after the total ingestion of 7 gm. (105 grains), gastric disturbances, such as pain in the epigastrium and nausea, developed, which disappeared, however, after lavage of the stomach. Hence, I would advise against the administration of the drug in such cases. Other substitutes for sodium salicylate or salicylic acid cannot be administered for long periods, as they produce depression of the circulatory system, or other toxic phenomena such as may occur from pronounced use of salol.

In experiments on my own person I was unable to detect any toxic effects after a dose of 5 gm. (75 grains) of aspirin, with the exception of violent headache and tinnitus aurium. The second dose of 4 gm. (60 grains), repeated in an hour, produced an increase of the frequency of pulse, a reduction of the temperature, and flashes of light before the eyes. At the end of about thirty-five minutes the symptoms disappeared, and were followed by violent headache. The tinnitus and headache persisted for about sixteen hours, and then subsided under the occurrence of profused sweats. I was able to detect salicylic acid in the form of salicyluric acid in the urine as late as fifty hours after the administration of aspirin. No exanthem developed even during its continued use.

My experiments on animals showed that the lethal dose in guinea-pigs is 1.5 gm. (23 grains) per kilo; death takes place from paralysis of the heart, and the pathologic appearances are identical with those caused by salicylate of sodium. At the commencement there was an increase in the pulse frequency, and a diminution of the hearing. After a time, however, there was slowing of the pulse and reduction of the blood-pressure; the respirations became superficial; Cheyne-Stoke's breathing supervened, followed in a short time by cessation of respiration. The poisonous effects are, therefore, the same as those observed in salicylic acid poison. Oltramore, in his pharmacological investigations of salicylic acid preparations, remarks that death was caused by cardiac paralysis. After death a marked hyperemia of the abdominal organs was demonstrated. The mucosa of the duodenum and of the small intestine were strongly hyperemic, and the seat of ecchymosis at some places. The kidneys also were very hyperemic. The urine contained albumin, which could be readily demonstrated by Heller's test.

The liberation of free salicylic acid in the stomach after administration of aspirin has been thor-

[1] *Therapeutische Monatshefte*, No. 5, 1899.
[2] *Heilkunde*, May, 1899.

oughly studied in artificial gastric juice by Dr. Wohlgemuth[1] in Professor Leyden's Clinic. In his article it is stated that the preparation is dissolved and decomposed with difficulty in dilute acids. He asserts that after two-hours' action of artificial gastric juice acid upon aspirin a very slight trace of free salicylic acid can be found, which is scarcely demonstrable by means of iron chlorid solution, as only a faint bluish color occurred upon addition of the solution. During the first two to three hours the solution and decomposition of aspirin proceded very slowly, and not until the end of three to five hours could larger quantities of free salicylic acid be detected in the stomach juice. In order to establish this fact *intra vitam*, I made a series of experiments on guinea-pigs. Three animals, each weighing two kilos. received each 0.5 gm. (7½ grains) aspirin at the same time. The first animal was killed after thirty-five minutes, and the fluid removed from the stomach, as well as from the duodenum, was subjected to examination. In the gastric and intestinal juices no reaction could be demonstrated. The second animal was killed after two hours, and the gastric and intestinal juices examined. The result was that in the gastric juice a very slight reaction was noticeable, while in the intestinal juice the reaction was very intense, so that the iron chlorid solution produced a strong violet color. This, so to speak, is pathognomonic, as it shows that the splitting up of the preparation first takes place in the alkaline intestinal juice. Further, it should be observed that the decomposition of the preparation in the alkaline intestinal fluid takes place after a few minutes. The slight reaction in the gastric juice, moreover, shows that a limited decomposition of the drug occurs in the stomach in the course of two hours, and that in cases of motor insufficiency of the stomach, gastric disturbances may ensue. It is generally assumed that it requires from two to two and one-half hours for the contents of the stomach to be carried into the intestines, and, hence, the view of Dr. Wohlgemuth is partly correct, provided there is present no disorder of the motor functions of the stomach. As a rule, it may be inferred that so small a quantity of free salicylic acid is incapable of evoking any gastric disturbances if the stomach is in a normal condition. The third animal experimented on was killed after three hours, and the gastric and intestinal juices subjected to examination. The reaction of the stomach contents was very weak, scarcely perceptible, since several tests had to be undertaken before a reaction was noticeable. In the intestinal juice the reaction was quite marked, although not as intense as in the animal killed after two hours, a proof that the decomposed preparation had already been partially taken up in the blood.

[1] *Ibid.*

These experiments demonstrated practically that aspirin is not split up into its components until it reaches the intestinal juice, and that it does not irritate the gastric mucous membrane. If we formulate the results of the above experiments we find that this preparation has the same therapeutic action as salicylate of sodium, with the advantage that it is more agreeable and does not disturb the stomach. The distressing tinnitus only rarely occurs under the administration of physiologic doses. In seventeen patients treated by me this symptom was present in only a single instance. The subject of the case was a young lady, sixteen years, old suffering from dry pleurisy. Aspirin was administered on the first day four times in 15-grain doses, without any after effects. On the second day after the administration of 15 grains of the drug the patient began to complain of troublesome tinnitus. The preparation was discontinued and atropin sulphate, $\frac{1}{150}$ of a grain, administered, and in one half hour later this symptom had entirely disappeared. On the following day the preparation was given in the same manner as before, but in a dose of 7½ grains. The day after I again increased the dose to 15 grains, and continued the use of the remedy in these quantities until the recovery of the patient, without noticing any further after effects.

At the commencement I administered aspirin in an alcoholic solution in doses of 15 grains, but after continued use for a few days in daily doses of 60 grains, symptoms of irritation of the stomach occurred, namely, a feeling of pressure in the epigastrium and nausea, so that the preparation had to be discontinued. This case was that of a woman thirty-four years of age, who during the past ten years had experienced four attacks of multiple polyarthritis. The symptoms (swelling of the joints, fever, and pain) subsided after six-days' treatment with salicylates, but the attacks recurred from time to time. I had an opportunity of treating the patient during her last attack, and employed salicylate of sodium with excellent effect. There was swelling of both knee-joints, and later the left humeroscapular joint was involved. Of course, in addition to the administration of sodium salicylate, the antiphlogistic method of treatment was adopted. The right knee joint, however, remained ankylosed after the subsidence of the acute inflammation, and it required three months' treatment by means of massage and hot baths until complete recovery ensued. Last month a fresh attack appeared which implicated the right ankle-joint. There was observed a daily temperature of

105° F. During this seizure aspirin was administered in 15-grain doses, four times daily, in an alcoholic solution, as this preparation is soluble in water at a temperature of 98½° F. only to the extent of one per cent. On the third day gastric disturbances, such as pains in the epigastrium and nausea developed. I introduced a stomach-tube and washed out the stomach with lukewarm water; besides this, I administered by the mouth $\frac{1}{60}$ of a grain of strychnin nitrate, together with $\frac{1}{6}$ of a grain of a morphin hydrochlorid. One half hour later the gastric disturbances disappeared, and the stomach contents withdrawn with a tube gave no reaction of free salicylic acid, as I was able to demonstrate by tests with dilute iron chlorid solutions. After three hours the preparation was again administered in alcoholic solutions, and the same disorders ensued. I, therefore, discontinued its use for twenty-four hours, and returned to the previous treatment, after which the disturbances subsided. At the end of this time I administered aspirin in wafers in 15-grain doses. No symptoms of gastric irritation appeared, and I was able to continue the preparation until recovery had taken place. On the ground of these experiments I would advise the administration of aspirin in wafers or mixed with some sugar.

One great advantage of this remedy over salicylate of sodium is that it is much more agreeable to take, and even during its prolonged use no aversion was experienced. As is well known, articular rheumatism is a protracted disease, and the discontinuance of salicylate of sodium is always followed by an exacerbation. By the administration of aspirin with sugar or in wafers it never becomes necessary to suspend the use of the drug in consequence of gastric irritation, and hence a cure can be obtained at an earlier period. The only disadvantage of the preparation is its insolubility.

I have treated three cases of dry pleurisy with aspirin, all of which were benefited by its administration. In a case of moist or exudative pleurisy aspiration had to be performed in consequence of the large effusion of fluid, and of the resulting dyspneic symptoms. The after-treatment consisted in the use of aspirin in daily doses of 60 grains, in addition to which tonics were administered. The patient improved with remarkable rapidity, and was discharged cured after three-weeks' treatment. In a case of pleurodynia no improvement was obtained from the use of aspirin, recovery taking place under hydrotherapeutic measures, massage, pulmonary gymnastics, and warm baths. In a case of intercostal neuralgia, as well as in a case of facial neuralgia, I employed this preparation without effect.

In acute articular rheumatism the remedy is a reliable antipyretic, and shortens the duration of the attacks. The pains diminish after a few doses, and the swelling diappears. But I would remark that the remedy is not capable of preventing recurrences. Of course, hydrotherapeutic measures must not be neglected. I administered aspirin in a few cases for periods of three weeks without the least concomitant effects. In view of the fact that in many rheumatic diseases lesions of the valves of the heart are encountered, we must be especially impressed with the value of aspirin. Depression of the heart occurs, as was shown by the experiments of Dr. Dreser on animals. This observer found that salicylate of sodium and aspirin when tested upon the isolated heart of the frog acted in a contrary manner. Koehler, in 1873, showed in his experiments on animals that sodium salicylate diminished the motor power of the heart in consequence of reduced excitability of the vagus branches. On the other hand, aspirin increases the motor activity of the heart, and in consequence of this influence cardiac collapse can be excluded during its use.

In cases of polyarthritis I found shortly after the administration of aspirin an increase of urea in the urine, while later the quantity diminished. During the use of aspirin in physiological doses I was unable to demonstrate albuminuria in a single instance, and even during its continued employment examination for albumin proved negative. In a case of sciatica treated with aspirin no perceptible improvement occurred. But I would point out that a single case is not sufficient to permit of a positive conclusion. In all cases of acute and chronic muscular rheumatism the remedy proved extremely serviceable, and produced a cure within a short time. The different cases exhibited but few features of interest, and hence I regard it as superfluous to give detailed reports of their histories.

In general, I would remark that aspirin is a most valuable substitute for salicylate of sodium for the following reasons: (1) Its agreeable taste. (2) Its freedom from irritating effects upon the stomach. (3) The absence of tinnitus aurium after the administration of physiologic doses. (4) The absence of cardiac depression. (5) The fact that it does not impair the appetite, even during prolonged use.

I feel certain that other investigators will be able to demonstrate the advantages of aspirin, and should the price not be too high it will soon displace salicylate of sodium.

Mortality in the Army.—General Sternberg reports that between May 1, 1898, and June 30, 1899, there died from disease 2774 men from typhoid fever, 476 from malarial fever, 359 from pneumonia, 342 from diarrhea and dysentery, and 185 from yellow fever.

SOME CASES BEARING UPON THE PERIPHERAL CAUSATION OF EPILEPSY.

BY FRANK H. EDSALL, M.D.,
OF MADISON, WIS.

ALMOST since the dawn of history we find mention made under various names of the disease which we to-day call epilepsy. Of old it was described as a devil which had entered into and taken possession of the mortal shell of its victim, and the contortions during a convulsion were said to be the struggles of the devil to retain possession of its tenement. Not an unjustified fancy for an age when so much that was otherwise inexplicable was explained on the basis of the influence of good or evil spirits, for even at the present day it would not require the play of a very strong imagination to convince one that the unfortunate in the grasp of an epileptic convulsion with his writhings and inhuman cries is struggling with a demon.

Such fancies must, however, give place in time to the advance of scientific information, and in the two thousand years that have passed since the Great Physician cast out devils we have learned at least that devils are not the cause of these attacks, but in view of the time and effort which has been expended all through that long procession of the ages, to the end that the mystery of this affection might be solved, exact knowledge of either its etiology, pathology, or therapy, is surprisingly small. With the hope, therefore, that some slight accretion to that knowledge may result I present a brief account of a few cases of this disease which have come under my notice in recent years, and beg to state in advance that it is not within the scope of this paper to enter into a critical study of epilepsy.

The first of the patients, M. H., aged twelve years, was the daughter of a prominent physician in the Northern part of Pennsylvania. At the time I first saw her, some five years since, she was a fairly well nourished girl of about the average size and development for her years, with no special evidence of a neurotic temperament. Her father being a physician of more than usual powers of observation he was able to give me a very minute history of her case. There was nothing as far as he knew in his own or his wife's family history which could have any bearing upon his daughter's affliction, the history of which is as follows: Ever since the real work of school had begun, in the patient's case some three years or so before, she had had at times evidences of epileptic seizures, which increased in frequency and violence with the increase in the amount of study demanded of her. Decrease in the amount of study or temporary removal from school diminished the frequency of the attacks but did not altogether abolish them. The period of their occurrence was somewhat variable, sometimes once or twice a week, again not more than that many times a month. Latterly the severity of the attacks had increased to such an extent that consciousness was lost during their continuance. Certain factors in the case had led her father to think that the child's eyes might be in some measure responsible, and to determine this point he brought her to me for examination. The question of a possible hysterical factor in the case was considered, but her father doubted its possibility and it seemed safe to exclude it.

Examination of the eyes showed vision in both to be less than 20/20, and examination by the ophthalmoscope showed the presence of a considerable refractive error. She was given a mydriatic to use, and further examination, with the eyes under the influence of the mydriatic, gave a refractive error of +2.00sph.⊖−2.50c. ax. 70° in O. D. +2.00sph.⊖−2.75c. ax. 160° in O. S. Glasses representing this were prescribed to be worn constantly. No abnormality of balance in the extra ocular muscles could be determined beyond a slight exophoria, about 3°, which was disregarded. I failed to hear from the patient again for nearly a year, at the end of which time she returned to me. After obtaining the glasses prescribed she had worn them faithfully and with greatly increased comfort. For two or three months after their use was begun she had had slight attacks of her malady but for some months there had been none. A maximum of out-door life was advised with as little study as possible for some time, with plain food and an abundance of sleep. Indirectly I heard from time to time that she was having no further trouble, but I did not see her again for nearly two years when as she was suffering somewhat from headaches I again tested her refractive state and slightly increased the strength of the cylinder for the right eye, and also made a slight variation in its axis. After this change was made there was no further trouble. I have seen her once since then, last summer. She was then in perfect health, had had no convulsion since the interval immediately following the time when glasses were first worn, and was in every way a contented young woman.

Another patient, somewhat similarly affected, was Mary X. of Washington, Pa., aged ten years. Her father gave a history of her having had several epileptic seizures within the year preceding her first visit to me. Her general condition was excellent. She was rather large for her age, and while not of more than ordinary intellectual power was not deficient. The convulsions were growing more severe and rather more frequent. No personal nor family history which seemed to have any bearing upon the

causation of the attacks could be elicited. Examination of the eye grounds showed no abnormality of either fundus. The muscular state of the eyes was as near orthophora as it well could be. Vision 20/20; slight hypermetropia. Under the use of a mydriatic she developed a hypermetropic astigmatism of 0 75 D. ax. 90° in the right eye, and 1.00 D. ax. 90° in the left eye. Glasses corresponding to this formula were prescribed and worn with such satisfactory results that when I next saw her, about a year subsequently, her father was able to report that there had been no convulsions in the interval.

The patient then disappeared from observation for about two years, returning, however, late in the fall of 1897. At this visit her father informed me that during that year the convulsions had again begun and were nearly or quite as troublesome as previous to the first visit to me. She had grown decidedly fleshly in the interval but was in excellent health. Her menstrual functions had been established during the year and were regular and painless. It was impossible to demonstrate any change in the refractive state since the glasses had been prescribed nor was there any heterophoria. I was obliged, therefore, to say that the case had passed beyond my ability to relieve it. What the subsequent history has been I do not know.

The third case in this list is that of Mr. S., a school teacher, from Indiana county, Pa., unmarried, aged twenty-eight years. He was rather ill-nourished and dyspeptic; was run down in health from overwork. He had never to his knowledge had any epileptic seizures but his history left little doubtthat he was a victim of nocturnal epilepsy, the bitten tongue and dulness and lassitude upon awaking making this most certain. He consulted me chiefly for relief from his severe headaches. His eye grounds were rather red and woolly, his vision 20/1. There was exophoria of 2°. Under mydriatics his refractive error was found to be a myopic astigmatism of 0.75 D ax. 90°. Glasses were prescribed to correspond to this error. Six months later I heard through his cousin, the physician by whom he was referred to me, that his headaches had disappeared, his general condition had improved and he gave no further account of having bitten his tongue during sleep. This was several years ago; what the course of the case has been since then I do not know.

The last case of the series, the one in which I expected to achieve most brilliant results and in which I was most disappointed, was that of a fourteen year-old boy from Washington, Pa. For two years he had had pronounced epileptic attacks of moderate severity and not especially frequent occurrence. He had a hypermetropia of 1.00 D. with an astigmatism of 0.50 D in the right eye and a similar error in the left eye. There was exophoria of 5°. The refractive error was carefully corrected, the muscular balance adjusted, and I composed myself to await the test of time as to results. I am still waiting, at least for anything favorable. It was four or five years ago that I first saw the patient. At the end of six months there had been no improvement, and then the parents began the wearisome round of all kinds of specialists, with no improvement whatever when I last heard from the case.

The first two cases and the last one bore the impress of genuine epilepsy. Both of the first mentioned occurred in young girls previous to but near the period of their first menstruation, the third in a boy about the age of puberty. All the patients showed a considerable degree of refractive error, the first one a high degree and a troublesome form. All were about at that period of school life when the work entailed is most confining and consequent mental activity increased and the resultant eye strain most troublesome. The adult case I will briefly consider later on.

With the history of these cases before us what do they teach as to the causation of epileptic attacks? Epilepsy may be described as a nerve storm arising from a central or peripheral focus, characterized by a more or less intense discharge of the motor nerve-cells as manifested by tonic and clonic convulsions, accompanied frequently by loss of consciousness.

With the class of cases in which a demonstrable central lesion is responsible for the convulsive outbreaks this paper has nothing to do, my consideration being limited to so-called idiopathic epilepsy. It is impossible in the light of our present knowledge of the pathology of epilepsy to say that epilepsy, purely peripheral in origin, ever occurs. It is most likely that all cases of it are dependant upon a central lesion of some sort, though this lesion may at times be so fine as to escape detection and of itself be unable to provoke the nerve-storm characteristic of this affection, the peripheral neurosis simply furnishing the determining factor in producing it. Under this theory the excessive demands made upon the inhibitory cells consequent upon the peripheral focus of irritation in time exhaust them to such a degree that they are no longer able to control the motor-cells which are in an unstable state, due to the (suppostitious) central lesion. Then a great wave of motor nerve-force is let loose and for the moment inundates the sufferer. These cells discharged, inhibition has time to recover control, and the unfortunate victim is temporarily free from a return of the attack.

In the first of the cases of which I have made men-

tion it is probable that the central lesion, whatever it may have been, was not deep-seated nor extensive, and that the relief from eye strain and the establishment of the menses, which followed not long after, sufficiently lightened the burden of the central nervous system to admit of the restorative forces of Nature repairing whatever trouble may have been at the bottom of the attacks, and thus the condition was permanently relieved. In the second case the condition which originated the convulsions was too permanent to be overcome, but was not at the time the patient was first seen sufficiently extensive to admit of its originating the convulsions unaided. With this peripheral factor in their causation no longer active the attacks subsided until the central lesions had advanced to a point where a peripheral determining factor was no longer necessary to produce the convulsion. In respect to the last case I need only say that while from its character I was justified in thinking it more likely that a peripheral irritation was concerned in the outbreaks than in almost any of the others, yet at the time, at least when I saw him, as the outcome of treatment proved, it was not in any way concerned therein. The third case was probably a mild form of epilepsy which doubtless followed the same course as did the first.

It is foreign to my purpose to take sides in the conflict which has been waged for some years between the advocates of graduated tenotomies in the treatment of epilepsy and those who denounce them as false teachers and heretics. As I understand it, the matter is somewhat like this: The tenotomists claim that graduated tenotomies furnish one of the chief if not *the* chief means of relief from this appalling affliction. Their opponents decry their arguments and statistics as misleading, and the spirit of brotherly love takes flight when the two sides get together, so heated is the controversy. The matter presents itself to me in this way: Asthenopia, due to refractive error, leaving out the question of whether it is causative or not, may at least determine an epileptic seizure. Muscular inequalities may produce asthenopia; therefore, why is it not possible for muscular asthenopia to determine such a seizure? The tenotomists in many instances have ridden their hobby so hard that they have been unable to read the signs by the wayside. It is a well-known fact that in many epileptics it is possible to bring about a temporary improvement simply by a change from one medicine to another. Analogously, it is possible that a tenotomy would temporarily benefit such as these remarkably, and, moreover, it is just possible that, even as a few years since some apt simulators succeeded in convincing even as bright minds as there are in the so-called School of Nancy, that mental suggestion, hand in hand with the application of a bottle containing a given drug, would produce the characteristic effects of that drug, so also it is possible that the statistics in connection with tenotomies in the cure of epilepsy may be similarly impaired. Personally, I do not believe that eye strain from any cause is responsible for the status epilepticus.

CLINICAL MEMORANDUM.

RAYNAUD'S DISEASE; WITH REPORT OF A CASE RESULTING IN DEATH.

By WILLIAM H. DUKEMAN, M. D.,
OF LOS ANGELES, CAL.

THE pathology of this unique disease is still obscure. Some writers define it as a vascular disease (Osler), while others class it as a disease of the nervous system (Starr, Dana), and still others as of vasomotor origin (Anders, Mitchell). Raynaud, however, defines the disease as a "neurosis characterized by an exaggeration of the excito-motor power of the cord presiding over the vasomotor nerves." Many writers do not recognize it as a distinct affection. So far as I can learn no autopsies have been made, the pathology thus far having been deduced from the symptoms.

The patient, a woman, was fifty-six years of age. She had passed the menopause some seven years before and was the mother of three children, all living and in good health. She had always been well until some four months before I saw her, when, after eating a hearty meal of fresh salt-water fish she had what she called an attack of acute indigestion, from which time, according to her statement, her health had gradually failed. Her family physician was called in, but no medication seemed to benefit her and she grew continually weaker during three months. On January 4, 1899, I saw her first. I found her confined to bed in an almost helpless condition. She complained of shortness of breath, cough and entire loss of appetite. She stated that soon after having eaten the fish she had felt sick and the next day had had severe diarrhea, which lasted for nearly a week, since which time she had been troubled with constipation and had grown weaker day by day until she was obliged to remain in bed.

On careful examination I could discover no reasons to account for her complete prostration. Her cough was simply a slight bronchial one; the lungs and heart were normal, there was no rise of temperature, her pulse was normal but the circulation was sluggish. There was no pain, no impairment of sensation to touch, the reflexes were normal, and there were no lesions of the blood-vessel.

I prescribed a little wine, a stomachic tonic and hot applications to her chest. Three days later she felt no better, in fact was not so well. Her cough had subsided, but she complained of a depressed feeling and the nurse informed me that she had passed a restless night, with unpleasant dreams, and the day previous had been more or less hysterical, with a tendency to cry and worry about her feeble condition.

As her left hand lay on her abdomen, I raised it and was examining the finger-tips with reference to the sluggishness of the circulation when she felt anumbness of the ring finger, but as there was nothing noticeable, I passed it by without a thought of its true nature. The next day I was called to see her as she had passed a restless night and when I entered her room she raised her left hand to show me her finger. The ring-finger was swollen and cynosed as far as the second joint; it seemed cold and dry. I pricked it with a needle, which did not cause pain, but a dark bloody serum-like fluid oozed from the puncture. For the first time I thought of Raynaud's disease. On examining the other fingers, her toes, and the entire body no other lesions were found, but the next day there were four symmetrical cyanosed patches varying in size from that of a dime to that of a 25 cent piece on the outer and lower side of the calf of the right leg.

Spells of transient loss of consciousness with sluggish circulation, depression of mind, anorexia, and a temperature of 97.2° F. occurred. In the meanwhile I had examined her urine. There was no albumin. no sugar, no tube casts, no blood, the specific gravity was 1028, and there was an excess of urates. The patient continued in apparently the same condition, but took more nourishment. In two weeks the skin of the affected finger had become necrotic, resembling dry gangrene, with a sharp line of demarcation at the second joint, and separating from the deeper tissues it peeled off, leaving a smooth, healthy surface. The patches on the leg gradually disappeared. Under treatment with tonics, the patient with returning appetite gradually grew a little stronger, and by the end of three weeks was able to walk to the balcony and sit in the open air.

About two weeks later her strength again gave way, with the same symptoms of depression and she was again confined to bed, and on February 12th I was summoned early in the morning to see her. The nurse reported that on awakening she had found her patient in a comatose condition. On examination I found a hemiplegia of the right side and on trying to arouse my patient discovered aphasia. There was now a local or symmetrical gangrene of the right ring-finger. My patient grew worse each day and on February 28th she passed into a deep coma and died three days later not having recovered consciousness.

I regret very much that I was not allowed to make an autopsy, for it seems clear that in this case some central nervous lesion could have been found to shed light on the pathology of this disease.

Dr. Byers of England, reports in the London *Lancet*, a series of cases in which he associates phthisis and Raynaud's disease. He concludes that in the disturbance of the peripheral circulation in Raynaud's and allied diseases, the pulmonic circulation is similarly affected in a phthisical patient, owing to the close connection between the vasomotor systems of the greater and lesser circulations.

In the above patient there appears to be good evidence of a central nervous lesion to a much greater extent than to cause a mere disturbance of the neurovascular system.

Erythro nelalgia, or Weir Mitchell's disease, is said by some writers to be only a less advanced stage of Raynaud's disease. But, on reading the clinical history of the two diseases, as related by Mitchell in his "Manual of Clinical Lectures on Nervous Diseases," the two affections appear to be entirely distinct.

In the case here reported there was no evidence of either disease prior to this attack. There were no symptoms pointing to any disease of the vascular system. The gradual failure of health due to toxin-poisoning, affecting the nervous system, and the final result all lead to the conclusion that in this case the pathology lay in the central nervous system, irrespective of the concomitant right-sided hemiplegia with aphasia.

MEDICAL PROGRESS.

The Dietetic Treatment of Tuberculosis—Dr. S. Schweiger (*Die Heilkunde*, August, 1899) states that in cases of pulmonary tuberculosis, in which ordinary foods can only be given to a limited extent because not well tolerated, the various nutritive preparations serve a useful purpose. Somatose has the advantage of being well tolerated, even in cases of acidity of the stomach, because it taxes the digestive functions to the least possible degree, since it consists of albumoses, or of predigested albumens, which undoubtedly have the same caloric value as that of native albumen. Both meat somatose and milk somatose are well borne by tuberculosis patients. These preparations should be prescribed in watery solutions, or as an addition to milk, coffee, cocoa, or soups. The author states in conclusion that the dietetic and hygienic treatment of this disease has given the most brilliant results in sanatoria.

Non-malignant Stricture of the Rectum.—Bacon (*Jour. Amer. Med. Assoc.*, September 16, 1899) says that gradual dilatation by bougies will not cure a true cicatricial stricture of the rectum, while it frequently increases the ulceration and may cause death from septic absorption or perforation of the bowel. The reason why it fails is that the excessive irritation which it sets up, causes a new formation of scar-tissue at the periphery of the old cicatrix. Forced dilation of rectal strictures with or without anesthesia was once a common practice, but the pelvic cellulitis and frequent deaths which followed caused the abandonment of this method of treatment. Internal proctotomy gives but temporary relief and the making of an incision in a septic field with no chance for free drainage is frequently followed by death. In complete proctotomy the incision is made through all the tissues including the sphincters and skin clear to the coccyx or sacrum. Here drainage is free and the operation is comparatively without danger, but as the wound heals by granulation the amount of scar-tissue is added to that preexisting and there is an additional danger of fecal incontinence. At one time it was hoped that strictures might be resected and the continuity of the gut reestablished by suture, but this operation was frequently followed by death due to the giving way of the sutures and the few

patients who recovered found that after one or two years the stricture had reformed. The rectum is buried in a bed of fibrous tissue so that the scar after anastomosis is constantly irritated. It therefore hypertrophies, and later contracts. Lateral anastomosis of the sigmoid into the rectum fails for the same reason. Bacon advises two operations which promise better results. If a stricture is at or above the levator ani muscle he performs a laparotomy and bends the sigmoid over the stricture and establishes an anastomosis between it and the rectum at a point below the stricture. After the fistula has become established the septum between the sigmoid and the rectum is clamped from time to time, the clamps being left in position two days or longer, until they cause atrophy of the septum. This is repeated until the strictured portion of the rectum has been thoroughly divided. If a stricture is below the levator ani, Bacon establishes a mucous fistula outside of the fibrous tissue of the stricture by passing an aneurism needle, threaded with heavy braided silk through the rectal walls around the stricture and back into the rectum above it. The thread is left as a seton and acts at the same time as a drain, so that there is no danger of infection. It remains in position two months during which time the bowel is washed twice daily with boracic-acid solution. The patient is then put under an anesthetic, the suture is removed, and a curved director passed along the fistulous tract. With a Paquelin cautery the stricture is divided. The success of this operation has been demonstrated in a number of cases.

Pulmonary Embolism Following Laparotomy.—BRACKETT (*Lancet*, July 29, 1899) publishes notes of a case of recovery after pulmonary embolism, the embolism occurring nine days after an operation for appendicitis. The anesthetic used was gas and ether. Respiration was not particularly good, and after the patient had been put to bed artificial respiration was used for twenty minutes. All went well for nine days and then the patient began to spit frothy bright red blood. There was no rise of temperature and no pain until two days later when vague pains were complained of in the right shoulder and side, shifting about from one place to another. Hemoptysis continued for seventeen days when further examination of the right side showed the presence of a moist pleurisy. Sleep from this time on was disturbed by severe night sweats. The pulse rose to 120 and the temperature to 102° F. On the following day an effusion took place into the pleural cavity and respiration was much oppressed. The aspiration of eighteen ounces of clear serum greatly relieved the patient. After removal of the fluid, the breathing, as heard at the inferior angle of the scapula, was markedly tubular. The temperature dropped to nearly normal. The hemoptysis gradually subsided and the right lung slowly returned to its normal condition. The attending physician was at first deceived into thinking that the lesion was a tubercular one. The question of ether-pneumonia was also considered, but the progress of the case excluded both diagnoses for that of pulmonary embolism, presumably from a clot formed at the time of operation, although at no time were there any sudden, urgent symptoms such as are usually seen under such circumstances. No special line of treatment was followed.

Aseptic Treatment of Abscesses.—NEVE (*Indian Med. Jour.*, August 16, 1899) thinks that in the treatment of abscesses surgeons have not made use of the best modern methods. The idea which has so long prevailed to postpone active measures until the last moment should be relegated to the past. His plan is to incise an abscess, break down all the divisions between the loculi with his fingers, and then rub the walls gently and thoroughly with gauze until the last swab shows no trace of pus or débris. The incision should not be too small. One should avoid making the incision close to any mucous surface or contaminating sore. When redressing, distension of the cavity with irrigating-fluid should be avoided. The incision should not be plugged as that favors the accumulation of blood or serum. It is important to remember that pus will not flow upward. In many cases primary union may be obtained by stitching the abscess. If any fluid accumulates it should be allowed to escape as soon as possible.

The Best Operation for Hemorrhoids.—STINSON (*Pacific Med. Jour.*, September, 1899) says that the best operation for hemorrhoids is performed as follows: The internal hemorrhoid is grasped with forceps and drawn well into view. A broad clamp is applied to its base pointing in the long axis of the pile. The clamp should be applied in such a manner that the portion remaining after excision shall suture conveniently. The pile is then cut away, and the open vessels separately ligated, and the edges of the mucous membrane accurately stitched with medium-sized catgut. One by one the piles are treated in this manner. No assistant is necessary and no speculum is used. The forceps themselves act as tractors and their pressure tends to control the hemorrhage.

THERAPEUTIC NOTES.

Diabetic Coma Relieved by Saline Transfusion.—OLIVER (*Lancet*, August 26, 1899) treated a patient in diabetic coma by transfusion of saline solution with the result that in a short time he was so far improved as to be able to walk about and take an interest in his surroundings although he was unable to return to work. This was the condition at the time of a former report (MEDICAL NEWS, vol. 73, p. 494) in August, 1898. By February, 1899, his thirst had again increased and he was passing five quarts of urine in twenty-four hours. There was considerable staggering due to incoordination. There was also considerable loss of muscular power, but sensation was unimpaired. On March 12, 1899, an attack of coma came on and the patient died in twenty-four hours. The result of the saline infusion was a lengthening of life free from coma for 243 days. Such a lucid period may be of tremendous importance to the patient and his family, if there are business affairs to be attended to.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, NOVEMBER 18, 1899.

THE REAL DURATION OF TYPHOID FEVER.

CONSULTING physicians are continually meeting with cases of fever in which the diagnosis has been made that the patient is suffering from infection by the bacillus of Eberth, and that the entire malady and the continuance of high temperature is dependent on this cause. Most of these physicians know full well that in a majority of instances the history of a very prolonged attack of fever indicates that the patient is not suffering from typhoid infection but in a considerable proportion of cases from infection by the bacillus tuberculosis. Without doubt a very common error in clinical medicine is the mistake of diagnosing tuberculosis for enteric fever. Further than this, it not infrequently happens that a patient convalescing from enteric fever develops some complication which maintains a febrile movement, and yet is considered an ordinary typhoid case, when in reality an accumulation of pus in some portion of the body is the factor which is retarding his convalescence.

The question then arises, how long is it proper for a physician to consider that fever is dependent upon typhoid infection alone? In reply to this question it may be said that the maintenance of febrile movement beyond twenty-eight days should always cause the physician to look for some complicating condition, and while in a certain number of cases this may not be found, in a large proportion some additional cause over and above the pure typhoid infection will be discovered. It will be remembered that the average duration of typhoid fever is after all in the neighborhood of from twenty-four to twenty-eight days, and as time goes by it becomes evident that notwithstanding diminished virulence of infection, increased resistance and improved therapeutic measures, the duration of the disease does not seem to be affected. The longest case seen by the late Austin Flint was fifty-eight days, and Musser has recorded a case in which there were no complications, but the temperature did not reach normal for seventy-three days.

Our attention has been called to this matter by an article by Dr. Hawkins and Mr. Thurston in the London *Lancet* of October 14, 1899. In this article they report a case in which the fever lasted for a period of 114 days, the patient finally convalescing after a brief relapse. A very interesting part of the history of this case is that the patient suffered from a perforated intestine but recovered after an operation had been performed for the perforation. This recovery after operation makes the case well worthy of report, but we doubt whether the typhoid infection should be considered responsible for the maintenance of fever for a period of 114 days. Surely there is sufficient reason to believe that other causes were at work, and if these had not been present a normal temperature might have been reached after a much shorter period. Whether we are correct or not in the belief that in this individual instance the typhoid infection was not entirely responsible for the prolonged temperature, the case at least affords us an opportunity of once more reiterating the conviction that prolonged fever occurring in the course of an illness from typhoid infection should not be regarded lightly, but should lead to a most careful and thorough examination of the patient for the purposes that we have named. Sometimes when there is no outward manifestation of the development of suppurative foci, an examination of the blood will reveal leucocytosis which, in its turn, will give us

reason to believe that a deep-seated abscess or inflammatory process is responsible for the condition.

STATE AID FOR THE TUBERCULOUS POOR.

DR. PEPPER used to say, "There are times in a doctor's life when he feels much more like writing a check for a patient than a prescription." This sentiment finds an echo in the doctor's heart when there stands before him one who needs freedom from care and worry, longer hours of rest and the possibility of living under favorable climatic conditions, but who alas, is not financially able to secure them, and to whom no permanent benefit can come from any combination of drugs however elaborate and theoretically efficient it might be. Since the present irresistible trend of medical thought with regard to the absolute curability of pulmonary tuberculosis, when treated under favorable conditions, has set in, this feeling of sympathy for the tuberculous poor has been strenuously emphasized.

As was insisted upon by a number of speakers at the meeting of the Section on Medicine of the New York Academy of Medicine, October, 17th (see this week's issue of MEDICAL NEWS, p. 663) we have come to the realization that the tuberculous poor die simply because they are poor. If they had the necessary means to enable them to give up work early in the disease and devote themselves only to the care of their health, there is not a doubt that numbers of them could either be completely cured, or their affection arrested, and years of useful life assured to them and to the State. This is the sad aspect of the case as it presents itself to the physician. This it is that must unite medical men all over the country in the movement to secure State aid by the building of State sanatoria for the tuberculous poor.

There is scarcely a country in Europe at present in which there is not, we shall not say a sanatorium, but a number of them, in which patients suffering from tuberculosis yet unable to pay for treatment are cared for. We need them in this country. The present state of affairs is a standing disgrace to our boasted progressiveness. There is of course some excuse for us in the aspect of the question that was expressed so well by Dr. Flick at the recent meeting. In a monarchy only the rulers need to be convinced of the necessity for some public good of this kind, while in a republic the whole sovereign people must be persuaded, or at least their legislative representatives. As a matter of fact, however, the present condition of affairs is due not so much to dilatory legislators as to the fact that the medical profession, as represented by medical societies, has not been a unit in its demands for action. Here in New York State, for instance, concerted action on the part of the various "powers that be" in the profession might have secured ere this the necessary appropriation for the erection and the maintenance of a sanatorium for the tuberculous poor. There is the crying need; there is also the remedy. Let us hope that by the time the State Legislature convenes certain differences of opinion that exist at present among medical bodies in the State as to what class of patients should first be helped by sanatoria, may be adjusted. Precious time is being lost. This is only too plainly shown by the account of the good accomplished by the first year's work in the Massachusetts State Sanatorium. The Empire State owes it to herself not to be behindhand in this matter.

ECHOES AND NEWS.

Women Doctors Not Wanted at the Front.—Miss Ward, M.D. volunteered to go to South Africa as a physician, but the Marquis of Lansdowne, Secretary of State for War, sent her a letter in which he stated that he was not prepared at present to allow women doctors to join the forces in the field.

Death from Chloroform.—Two cases of death from chloroform are reported from Hong Kong. In one the Khrone and Sessemann regulating inhaler was used, and in the second a Skinner inhaler. In the first case not quite a dram of chloroform had been used, and in the second about ½ an ounce, so that in both instances death occurred early in the process of narcosis. In neither instance did autopsy reveal any efficient cause for the unfortunate result.

Hospital Assistants for the Boers.—While American women in England and America are fitting out a hospital ship for the care of the British and Boer wounded who may reach the coast, a society of French women has organized a field hospital at the cost of $2500, which left Marseilles for Delagoa Bay on the way to Johannesburg November 6th. Subscriptions for the Boer wounded are supplying ample funds in Paris for the equipment of additional hospitals. It is said that large numbers of medical students are setting out from Paris for the Transvaal.

An Army Medical Chest.—An excellent surgeon's kit has been devised by Major George E. Bushnell, Assistan Surgeon-General on the staff of Surgeon-General Stern-

burg. It has been found especially useful in the war in the Philipines, where numbers of small bodies of men are detailed on special expeditions or for garrison duty in out-of-the-way places. The kit is contained in a strong chest, two feet long by fourteen inches deep and wide, which one man can carry anywhere. Of these handy portable outfits for field service 150 sets are being made to send to Manila for use in the active and divergent operations of our troops.

Big Death-rate in Chicago.—The weekly bulletin of the Health Department says: "It is evident that 1899 will rank among the most murderously epidemic years." The bulletin adds that epidemics of contagious diseases, especially diphtheria and scarlet fever, have been more prevalent and more fatal than at any time since 1885, and the deaths among the aged, those over sixty, are largely in excess of the average. This latter, it is said, is due to the prevalence of influenza in the early months of the year, but the increase of diphtheria deaths is attributed to what the bulletin styles "an unaccountable neglect of the antitoxin treatment."

Deaths Not Due to Vaccination.—The State Board of Health at Albany reported on November 8th concerning the deaths of two children, one at Brewsters near Newberg, the other at Geneva. These deaths were said to be the results of compulsory vaccination. It was found that their deaths were due to the neglect, ignorance and filthy habits of the parents, and failure on their part to carry out the instructions of the physicians who performed the vaccination. One child died of tetanus, the other of "blood poisoning." The parents of one child failed to remove the soiled bandage and kept piling others on the arm until no less than seven were counted.

Epidemic of Typhoid at Lexington, Ky.—Nearly forty students of Kentucky University, located at Lexington, have typhoid fever, and it has become necessary for the faculty to take decided steps toward checking it. The students have been sent to the Good Samaritan Hospital, but since there is no more room at that institution it has become necessary to care for them at their boarding-houses. Two students have died. The cause was at first attributed to the water, but now some members of the faculty believe it was due to milk from cows fed on distillery slop. President Cave says the epidemic has been checked, and there is no further cause of alarm, and that every one of the patients is now rapidly improving.

Beer Consumption.—A writer in the *North American Review* declares that a great deal of beer is consumed in order to satisfy a craving for the elements which are eliminated from wheat in the making of white bread. However this may be, the large amount of this drink which is disposed of would indicate something more than an appetite merely for alcohol. In Germany, during 1897 1,383,700,000 gallons of beer were consumed; 1,192,000,000 gallons were drunk in Great Britain; 180,000,000 in France; and about 90,000,000 in Russia. Estimating "per head," it is reckoned that 36 gallons are drunk in Belgium, 32 in Great Britain, 25 in Germany, 21 in Denmark, 12 in Switzerland, 10 in the United States, 9½ in Austria-Hungary, 9 in Holland, 5 in France, 3½ in Norway, 2½ in Sweden and 1 in Russia.

A Rat-trap for Plague-infected Rats.—In view of the continual danger from the plague that exists, the following notice from United States Consul Heenan at Odessa seems of practical interest: "I saw the other day a curious device attached to the mooring-rope or cable of a steamer which was loading at this port (Odessa). The cable was run through a piece of iron pipe about a foot in length, and welded on the end of the pipe was a flange or funnel which looked like the end of a trumpet, with the wide end facing the ship. The iron pipe was stuffed with oakum, to prevent it from slipping and also to prevent rats from passing through it. This novel construction was quite close to the ship. The Russian authorities furnished these appliances and obliged all ships to use them whenever they came from a port infected with the plague, in order to prevent the rats on the ship from coming on shore. These devices are attached to each cable by which the ship is moored. In addition to this precaution, the master of the ship is obliged to take down his loading stages every night and erect them again the following morning, in order to prevent the rats from coming on shore during the night."

Death-rates in Cities and States.—According to records for the year 1898, compiled by the Marine Hospital Service from official reports, the most healthful town in the United States was Millerstown, Pa., where the death-rate was less than 1 per 1000 of population. The most unhealthful town was Liverpool, New York, where the death-rate was 44.17 per 1000. The most healthful city is Homestead, Pa., which had a death-rate of 2.70 per 1000. Of the very large cities the most healthy was Cleveland, Ohio, where the death-rate was 13.63. The most unhealthful large city was New Orleans, of which the death-rate was 26.91. Other large cities and the respective death-rate mentioned in the official record are: New York, 19.28; Boston, 20.09; Baltimore, 19.10; Washington 20.74; Chicago, 14.08; St. Louis, 14.28; San Francisco, 19.41. The twin cities St. Paul and Minneapolis had a death-rate of only 9.16. The most healthful state seems to be Nebraska, where the average death-rate of the cities and towns was only 6.24. It is noticeable that the most healthful conditions are found in the Northwest and the region between the Mississippi River and the Rocky Mountains. The death-rate in South Dakota was 7.36; in Minnesota, 9.08, in Wyoming, 8.33; in Iowa, 8.83; and in Colorado 10.86. In California, where the climatic conditions are supposed to be favorable to health, the death-rate was 16.26.

The Bubonic Plague.—The march of the plague goes steadily on. In India for the week ending October 7th the reported deaths reach a total of 6727, or over 1000 more than the total of the previous week. The Bombay Presidency is still the seat of the disease. As has been

previously announced, the disease has begun to attack the Europeans; on October 12th there were nine Europeans in the hospital suffering from plague. Colonel Hay, one of the medical officers on plague duty in Poona district, has recently died of the disease, and Mr. Bromley, the prosperous dentist of Poona, has been stricken down. For the week ending October 26th, 89 fresh cases of plague, with 72 deaths, were reported in the Island of Mauritius. The report that 10 cases of plague had been discovered at Lorenzo Marquez, Delagoa Bay, has been officially confirmed. The suspicious cases reported from Santos and San Paulo, Brazil, have been confirmed as genuine cases of bubonic plague. There is no longer any doubt, therefore, that the plague has actually reached the American continent. The filthy condition of Santos offers no hope of the disease being suppressed. The plague at Alexandria may be considered as practically at an end. Whether or not this report has been put forth for the purpose of clearing the way for the great inrush of winter visitors to Egypt, it is certain that the plague has run a mild course, only seventy-one cases in all having been reported. The sanitary authorities under Sir John Rogers have achieved a remarkable success at Alexandria for which the civilized world owes a debt of gratitude. News of the plague is evidently being suppressed at Oporto. Four fresh cases reported October 24th give the latest information from that quarter. Late reports from Algeria announce that the plague has appeared at Philippeville and Bougie, where the Government is taking active measures to localize it.

MEDICAL MATTERS IN NEW YORK.

DEATH FROM BERI BERI — A DINNER PARTY AT DR. POLK'S—DRUGGISTS WHO MAKE SUICIDE EASY—SMALLPOX IN BROOKLYN — DEATHS OF DRS. BLEEKER AND M'CREERY — ST. JOHN'S GUILD—THOUSANDS LEFT TO CHARITY — A MAN WITH TWO HEARTS—AMERICAN PERSONNEL OF THE HOSPITAL SHIP "MAINE."

NICHOLAS FERNANDEZ, the second cook of the British steamship "Needles," lying at Erie Basin, Brooklyn, died on November 9th, of beri-beri.

Among the pleasant and interesting occasions that are gracing the social functions in the profession at the opening of the present season was the dinner recently given by Dr. William M. Polk at his residence to Dr. Friedrich Kraus, Jr., of Carlsbad, Germany. Twelve covers were laid; and the evening passed pleasantly with the narration of many Carlsbad experiences and the consumption, among other beverages, of bottled American waters.

President Murphy of the Board of Health is seeking to enforce the State law relative to the sale of poisons. If the Board has no power under the present law to proceed against druggists who make suicide easy by failing to ask questions of poison purchasers, Colonel Murphy has decided to ask for the adoption of a corporation ordinance that will cover the case. Suicides are becoming unduely prevailent in this city, and the manner of self-destruction is usually that of swallowing poisons bought at drug-stores.

Mary Loftus, a negress, employed as a servant at 58 Downing street, Brooklyn Heights, was removed to North Brother's Island on November 11th suffering from smallpox. She is the sister of a negro man who was employed by a Fulton street dental firm to give out handbills in front of the place of business. This negro had variola for two weeks before the Health Department knew of it, and all that time he continued at his work of giving out bills to the shoppers who thronged by him. He communicated the disease to his relatives; Mary Loftus is the eighth victim. She has been moving about in the neighborhood where she was employed, conversing with other servants and visiting the shops. The Health Department is maintaining a careful watch to prevent further speading of the disease.

Dr. Edward Bleeker died at his home in Whitestone, Borough of Queens, on November 5th. He was born in Albany in 1844, and was a direct descendant of Yan Yancy, the first Recorder and second Mayor of Albany. He studied for one year at the Albany College of Medicine, after which he entered the College of Physicians and Surgeons in this city, from which he was graduated in 1865. He at once began service at the State Barracks at Albany, where several thousand wounded soldiers were quartered. He was for twenty-five years a member of the Whitestone Board of Education, and in several other ways manifested his good qualities as a citizen. He was one of the promoters of the Flushing Hospital, and the first President of its staff physicians.

Dr. John G. McCreery, forty-nine years old, died at his home in this city on November 10th. He was graduated from Bellevue and the Royal College of Surgeons, London. Besides being a well-known physician he was a Catholic of prominence and a member of the University Club. He was a visiting surgeon at St. Vincent's Hospital.

The Forty-third Annual Meeting of St. John's Guild was held on November 8th. The two most important events of the past year were the building of a new floating hospital and the erection of a four-story structure at the Seaside Hospital. During the season 62,672 women, children, and babies, enjoyed excursions upon the boats, and 3799 patients were treated. For the first time in the history of the Guild patients from Harlem and from Brooklyn were received on the floating hospitals to the number of over 13,000.

By the will of Henrietta Martin of New York $50,000 are bequeathed to charity. Among the institutions benefited are St. Luke's Home for indigent Christian females, the West Side Day Mission, and the Home for the Relief of the Destitute Blind. By the will of John O'Brien, the New York Banker who died recently, the New York Foundling Asylum receives $2000, St. Vincent's Hospital $2000, and St. Joseph's Home for the Age $1000.

Some time ago a newspaper man was complimented in this column upon what appeared to be a rather brilliant flight of fancy on the subject of "a man with two hearts." The present writer is now able from his own observation to pay this newspaper man a still higher compliment. The statements made were all within the facts. Probably no one can appreciate more fully than can a

newspaper man the value of this latter compliment. The other day an elderly negro called on the writer and wanted to exhibited himself. On the left side of his chest the usual first and second heart sounds were heard. Then the writer placed his hand over the left precordial region and putting his stethoscope on the right side he heard a first and second sound quite distinct from that felt on the left side. Then the negro proceeded to juggle with his "innards" until a tumor almost the size of a quart measure appeared in the left inguinal region. The writer placed his stethoscope over this region and heard distinctly a first and second heart sound. Then the negro manipulated his right side in the same manner and a tumor appeared in the right inguinal region. The writer put his stethoscope over this region and again heard a first and second heart sound. The examination having transpired an evidently anticipated emolument was bestowed. Any colleague who is willing to act in like manner would, no doubt, have an opportunity to examine this interesting freak, whose name and address is William King, 53 Fulton street, Brooklyn. Possibly the teratologist may be able to explain this odd state of affairs. Mr. King has already arranged for the examination of what remains after his soul has left its physical habitat; and in the course of time we may expect a scientific paper of no little interest upon this case.

The steamship "Mesaba" of the Atlantic Transport Line sailed on November 12th, having on board the first instalment of the American personnel for the hospital ship "Maine," which the Association of American Ladies in London, represented by Lady Randolph Churchill, is sending to South Africa. In the party are three surgeons—Drs. G. E. Dodge and H. H. Rodman, both of this city, who have been assistants of Dr. McBurney at Roosevelt Hospital, and Dr. C. H. Weber of Philadelphia, whose appointment was warmly recommended from personal knowledge by Dr. John S. Billings of the United States Army. They are in this party five nurses, Misses Hibbard, Ludekins, Manly, McPherson and McVean. The surgeons have taken with them an ambulance selected by General Francis V. Greene as the latest and best product of American army experience. It is sent as a gift of Mrs. Whitelaw Reid, to whom Lady Randolph Churchill and her English associates have intrusted the work of selecting the American personnel for the hospital ship. This ambulance was constructed after designs made by Major E. T. T. Marsh. It will accommodate four wounded. At the instance of Mrs. Reid, the Secretary of War has granted leave of absence to Major Julian M. Cabell of the Medical Department, in order that he may accept a position as surgeon on the "Maine." About thirty more nurses—a number of whom will be male nurses — sail for England on November 18th. Two apothecaries will also be sent. It is reported from London that Colonel F. Henderson, late of the Second Life Guards, has been appointed chief medical officer in charge of the hospital ship "Maine."

The Health Department submits the following report of contagious diseases for the week ending November 11, 1899: Measles, 262 cases, and 10 deaths; diphtheria, 248 cases, and 37 deaths; laryngeal diphtheria (croup), 11 cases, and 4 death; scarlet fever, 109 cases, and 6 deaths: smallpox, 1 case; chicken-pox, 15 cases; tuberculosis, 172 cases, and 148 deaths; typhoid fever, 56 cases, and 17 deaths; cerebrospinal meningitis, 9 deaths.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

DR. T. M. ROTCH ON INFANT-FEEDING—PHILADELPHIA ACADEMY OF SURGERY—DR. MORDECAI PRICE ON THE MORTALITY IN APPENDICITIS.

PHILADELPHIA, November 13, 1899.

DR. T. M. ROTCH of Boston addressed the Philadelphia Pediatric Society at its last meeting, held November 10th, on the subject of "Some Difficulties in Prescribing and Modifying Milk for Infant-Feeding." The speaker first dwelt upon the importance of milk modification in the case of the individual child, for the reason that different infants have such widely varying degrees of digestive powers that one fixed modification is unsuited in many instances, to the individual case. The common statement that milk must be withheld from the child in many diseases to which infancy is prone was, according to Dr. Rotch's experience, wholly incorrect; and, on the contrary, correctly modified milk was thought to be the most suitable food in nearly all cases, not excepting even summer diarrheas.

Improper and inexact methods of modification were held responsible for a great amount of harm, and to these causes many practitioners may attribute their lack of good results. The difficulties which the physician has to meet with in the home modification of milk are serious ones. The milk, as it is delivered to the house of the consumer, is often diluted with water; the cream of different milks, or of the same milk on different days, may contain varying percentages of fats; a 5 per cent. cream from different cows used to make 2 per cent. fat mixtures may thus make the mixture range from 1.45 per cent. to 2.66 per cent. of fats. If the physician cannot personally make the proper modification, and this is obviously impossible in the majority of instances, the mother or the nurse may add a little more cream than the formula directs, "so that the baby may not be starved," as she is wont to express it. This "little more" may mean an increase of from 4 to 10 per cent. of fat in a mixture containing 20 fluid ounces. Regarding the presence of micro-organisms and their products in milk, the speaker declared that he did not believe that heating milk in which bacterial toxins have already developed destroys these toxins, and therefore such milk is not fit for use.

Referring to the various sources of the milk-supply, Dr. Rotch remarked that "contracted milk," from a large, properly conducted dairy, is the safest to employ, most of the epidemics arising from the use of poor milk having been traced to a small herd of cows, or in many instances to a single cow. Milk and cream should be analyzed by experts before being pronounced fit for use, and physicians should seek to educate the

people to recognize the value of this procedure, and to pay the increased cost of certified milk, for the sake of their children's health and welfare.

At the conclusion of his address Dr. Rotch was tendered a reception by the Society, which was largely attended by representative medical men of this city and environs.

At the last meeting of the Philadelphia Academy of Surgery, held November 6th, Drs. H. Augustus Wilson and J. T. Rugh reported two cases which they believe to be unique in the literature of orthopedic surgery, each being an instance of an anomalous spinous process of the seventh cervical vertebra, which articulated with the left scapula. Both cases were observed at the Jefferson Medical College Hospital within two weeks of each other. The first case, that of a girl of seven years, was supposed to have a birth-injury, followed by signs of pressure paralysis, the general appearance being that of torticollis; the left arm was 1½ inches shorter than the right, and could not be raised over the head; a diagnosis of anchoring of the scapula to the spine was made in this case. The second case, a girl of eighteen, presented the following physical signs: the left shoulder was higher than the right, and the left scapula was 1½ inches nearer to the spine than the right, motion being limited as in the preceding case. Both cases were operated on by Dr. Rugh, and the supernumerary body removed though an incision made over its site. The bone removed from the second case was two inches in length, by 1¾ inches in circumference; it had an articular surface at the scapular end, but was attached to the spine by an osseous union, apparently causing a division to the left of the seventh cervical vertebra; there was, however, evidence that at some preceding period there had been a fibrous union at the spinous end of the bone. The specimen removed from the first case was 1¼ inches long, by 1⅛ inches in circumference and showed at the spinal end two tuberosities having articular surfaces, the scapular end possessing a single articular surface; the anomalous processes seemed to occupy the place of the regular spinous processes, there being no sign of the latter's presence in either this, or in the other case. The results of the operation were most favorable in both instances, and at the present time, by the use of gymnastic exercises, the normal motion in both patients is almost entirely regained.

At the same meeting, Dr. Joseph M. Spellissy reported a "Case of Removal of the External Two-thirds of the Gasserian Ganglion, with Preliminary Ligation of the External Carotid Artery." The patient had suffered from intense neuralgia for the past nine years, for the relief of which the infra-orbital nerve had been removed four years ago, and also the inferior dental nerve at a later period; neither of these operations afforded permanent relief from the pain. The operator, after seeing such severe hemorrhage from the middle meningeal artery during the operation for Gasserion ganglion removal, decided to ligate the external carotid artery, as a preliminary to the intracranial maneuvers. This procedure accomplished, a skin flap was made reaching down to the zygoma, in order to reach as near the base of the skull as possible. The external two-thirds of the ganglion was dissected out, cut, torn, and curetted away, no hemorrhage from the middle meningeal being encountered. A little fluid kept collecting in the field of the operation, but nothing approaching in nature a hemorrhage was met with. The double operation occupied about two hours, ether being used. The flap was carefully kept warm during this time, and showed no evidences of sloughing, union by first intention being secured. As a result of unavoidable division of the motor branch of the fifth nerve, unequal action of the lower jaw was noted as a sequel to the operation. The patient declares that there has been but a single twinge of pain since the time of the operation, the middle of last July.

Dr. Mordecai Price, at the last meeting of the Philadelphia County Medical Society, held November 8th., delivered an emphatic argument in favor of the surgical treatment of appendicitis, under the caption, "Treatment of Appendicitis, and Its Great Mortality." Among the aphorisms voiced preliminary to the speaker's consideration of the operative technic, were, among others, of equal emphasis: "Medical treatment does not cure genuine appendicitis;" and "The recovery of a case through rupture of an appendicial abscess through the colon, or through the bladder, is an accident, and does not form a basis for treatment." As to the method of operation, Dr. Price preferred to use a short, oblique incision, parallel to the crest of the ilium; the appendix should be amputated, if possible about ¾ of an inch from the head of the colon; if an abscess was found it should be ruptured with the point of the finger, and thorough irrigation of the abscess cavity, and of the general peritoneal cavity, practised, with plain, sterile water. The view was expressed that the morality-rate of the "younger" surgeons of to-day increases as they deviate from the rule of Tait, who, by the free use of boiled water in flushing out the abdominal cavity, secured the lowest average death-rate attained by any abdominal surgeon. Gauze drainage, removed small pieces at a time, should be used, and the wound allowed to heal from the bottom. After the operation irrigation should not be performed, but in the event of pus forming the wound must be explored and new drainage introduced. Dr. Price's statistics included 111 cases, of which 2 were fatal. Of the 109 recoveries, in 1 case a slight hernia followed the operation. Dr. Price in closing expressed his belief that the mortality-rate of the average operator (7 to 20 per cent.) was entirely too high, attributing this to faulty technic; he advised, as essentials for a better mortality-rate the following: free movement of the bowels before operation, thorough irrigation of the abdominal cavity, gauze drainage, and intelligent after treatment.

The total number of deaths in this city for the week ending November 11th was 314, this being a decrease of 67 from those reported last week, and a decrease of 83 from the corresponding week of last year. Returns of infectious disease show that there occurred during the week 36 new cases of enteric fever, with 8 deaths; 68 cases of scarlet fever, with 4 deaths; and no less than 117 new cases of diphtheria, with 24 deaths.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

EFFECTS OF VERATRINE UPON THE MYOCARDIUM—SPASMUS NUTANS—LECTURE BY DR. ADAMI—APPROPRIATION BY CHICAGO CITY COUNCIL FOR MEDICAL INSPECTORS—PROVIDENT HOSPITAL REPORT—VITAL STATISTICS—COLONY FOR EPILEPTICS—NEW LABORATORY FOR COOK COUNTY HOSPITAL—SANITARY ASPECTS OF DRAINAGE CANAL—CHICAGO MEDICAL SOCIETY—FACE PRESENTATIONS—SIMPLE HYPEREMIA AND INFECTION OF THE BREAST IN CHILDBIRTH — OVARIAN CYST COMPLICATING LABOR.

CHICAGO, November 11, 1899.

AT a recent meeting of the Chicago Society of Internal Medicine, Dr. S. A. Matthews presented a paper on the effects of veratrine upon the myocardium. First, he dealt with the effect produced by this agent upon the irritability of the heart-muscle; second, its effects upon the contractility of the heart-muscle; and, third, its effects upon the circulation produced by the changes in the irritability and contractility of the myocardium.

DR. I. A. Abt followed with a paper on spasmus nutans, in which he reported two interesting cases, and dwelt upon its confusion with allied diseases, *e. g.*, eclampsia nutans. He referred to confusion of nomenclature, and gave the reasons for retaining the term spasmus nutans. The etiology, prognosis, diagnosis, and treatment were referred to at length.

On November 29th the annual lecture before this Society will be delivered by Dr. J. G. Adami of Montreal, Canada.

At the last meeting of the Chicago City Council $4750 was appropriated for the employment by the Health Department of ten medical inspectors at a salary of $75 a month, and ten disinfectors at a salary of $83.33 a month. This was passed as an emergency appropriation upon the recommendation of the Commissioner of Health.

At a recent meeting of the Board of Trustees of the Provident Hospital, the annual report showed that 415 patients had been received during the last year, 183 of whom were colored and 232 were white.

According to the bulletin issued by the Health Department last week, the number of deaths from all causes (381) is the fewest since the week of December 10, 1898. However, the situation is not at all satisfactory. The summary of deaths by ages, sexes, and causes shows a continued excess of diphtheria, scarlet fever, measles, and whooping-cough, and the number of reported cases of these indicates their almost epidemic prevalence. Their contagion is more widely spread than at any time since 1885, as shown by the records, and there is reason to fear that the same is true of smallpox throughout the country generally. This latter disease has prevailed extensively longer than a year in so mild form as not to attract enough attention to cause the usual preventive measures to be enforced. The result has been the sowing of the contagion broadcast, and it only awaits favoring conditions to develop an epidemic.

At the meeting of the Conference of State Charities, it was urged that a strong committee go before the next Legislature with the statement that the only provision Illinois makes for her epileptics, suffering from a malady which almost renders them social outcasts, is the insane asylum. Here the conditions of their commingling with the feeble-minded work injury both to the epileptic and the insane. The request will be for an appropriation to purchase 1000 acres of land for the purpose of a colony.

A new and well-equipped laboratory in a separate building in connection with the County Hospital has been vigorously advocated by one of the County Commissioners, who estimates the cost of the building at $15,000. He will endeavor to have it constructed next year if the county finances warrant it. It is well known that the present laboratory is too small and too poorly equipped to meet the needs of so large a hospital.

At the last meeting of the Physicians' Club of Chicago the drainage canal was the subject for discussion. The sanitary aspects were dwelt upon by Commissioner Reynolds, and among other things he said that analyses of water in the Illinois River have established that there will be no pollution of the river following the opening of the drainage channel. Concerning the effect of pollution of the water-supply upon mortality statistics, he said the analyses which the Health Department has been making for the last two weeks have shown that increase in mortality records follow the pollution of the water with mathematical regularity. The Physicians' Club adopted a resolution commending the plan for medical inspection of school children.

At a meeting of the Chicago Medical Society, held November 8th, Dr. Gustav Kolischer read a paper on modern treatment of face presentations. The diagnosis and prognosis were dwelt upon at considerable length, and then the indications for interference, preparatory measures and operative delivery.

LITERARY NOTES.

ALEXANDER THE GREAT A SUFFERER FROM TORTICOLLIS.

IT has always been a subject of remark that practically all of the statues and busts of Alexander the Great which have come down to us represent him with his head thrown slightly back and partially rotated, his eyes turned upward. The traditional and conventional explanation for the attitude has been that the young conqueror, satiated with earthly glory, was represented by the many sculptors to whom he gave sittings as gazing heavenward as if sighing for other worlds to conquer. Professor Benjamin Ide Wheeler of Cornell, whose "Life of Alexander" running at present in the *Century* is attracting deserved attention, points out, in one of the recent contributions, that the attitude of Alexander in all these reproductions is exactly that of a man suffering from torticollis, and that there are good historic grounds for the belief that Alexander was a sufferer from that affection.

Julius Cæsar is said to have suffered from epilepsy. French physicians are of the opinion that there is enough evidence in Parisian tradition to justify the belief that

Napoleon also suffered from occasional attacks of the mal comitial. Now comes evidence that Alexander was a sufferer from a nervous affection probably grafted, as torticollis so frequently is, upon a strong nervous heredity. Here is material for an essay on genius and a degenerate nervous system.

DR. WYETH'S LIFE OF GENERAL FORREST.

At the beginning of September Harper and Brothers issued this interesting excursion in biography by our well-known New-York surgeon. Some chapters of it have already appeared in *Harper's Monthly*, and have attracted no little attention. Dr. Wyeth writes most sympathetically, and with a story as full of thrilling incident as is the life of Forrest, makes, as might be expected, an extremely interesting book. The great cavalry leader of the South deserved the tribute of a special biography here accorded and has been fortunate in the biographer fate allotted him. Now that North and South are drawing closer together, and the younger generations stand shoulder to shoulder once more, the tale of the capture of Fort Pillow, with the unfortunate incidents that followed it, as told by Dr. Wyeth, is especially timely. The so-called massacre, after the surrender, especially of the colored troops fighting in the Northern cause, has always seemed in history an awful blot upon the fair honor of Southern chivalry, and a stain upon the military glory of the brave Southern commander. There was an unfortunate set of circumstances that led to the killing of brave men. In the moment of excitement after the successful assault absolute restraint was impossible. The invitation to surrender had been categorically refused. An excited soldiery went farther than was necessary with the battle, but massacre after surrender there was none, as no surrender was offered.

LONDON DOCTORS AND THEIR WORK.

The *Eclectic Magazine* for September contains a very interesting article on this subject that originally appeared in the London *Temple Bar Magazine*. Some of the personal bits in it are decidedly quotable. For instance, Sir James Paget is reported to have said to a young man who came to him for advice as to how to get a consultant practice in London: "Put up your brass plate and then go away for five years," a piece of advice quite as applicable and practicable now as then, and, alas! painfully near the mark.

A distinguished physician is quoted as having recently complained that there were three prescriptions which he wished almost daily to give, but which no living chemist could compound: (1) Sunshine for those who cannot go abroad. (2) Rest for those who need it and cannot get it. (3) Work for those who are ill for want of it.

London doctors are evidently much more rushed than their brethren on this side the water. Some of them it seems have to make the change from morning to evening dress while riding about in their carriages. One doctor complains he has had two dress suits stolen from his carriage in three months. A physician, the occupant of a carriage that was run into by an omnibus, was disclosed dressed all in white. There was danger of his being apprehended as not of sane mind until he explained that he was on his way from Euston station to Park Lane, and was dressing for a dinner party.

THE "SCIENTIFIC" FRANKLIN.

No side of the many-sided Franklin is more interesting than the one depicted by Paul Leicester Ford in the September *Century*,—Franklin as a scientist. Few Americans realize what a large figure in the science of his time and of all time our Franklin was. We are apt to think of him as a printer who dabbled in many things more or less scientific, and by a fortunate accident discovered the identity of lightning and electricity. As the brilliant theorizer in science, anticipating a number of discoveries, as the acute observer with a passion for proving things experimentally, his countrymen do not know him. He was the first typical American inventor, and is a worthy type of the race in much more than that. There is a characteristic anecdote of his carrying a partially hollow cane filled with oil in order to be able to test in various places during his travels through England the effect of oil upon troubled waters.

SOME PRAIRIE CHUMS.

Dr. Woods Hutchinson, at present in London, and serving as correspondent of the MEDICAL NEWS, has an interesting article with this title in the September *Contemporary* (of London) that is written in the sympathetic vein so modish now in books on animals. We venture one quotation from it: "Like ourselves all the animals are beautiful at least once in their lives, in the first days of their existence, and this is true of even such unpromising specimens as the wolf, the pig, and the donkey." The article is interesting, especially as showing that an ardent advocate of animal experimentation as Dr. Hutchinson has always consistently been, may not be lacking in sympathy for animals, though it does not degenerate into maudlin sentiment.

PATHOLOGY IN WORKS OF ART.

Some years ago Professor Charcot of Paris pointed out that the pictures from medieval times representing people "possessed by the devil" very often really depicted patients in typical hysterical attitudes. Copies of numerous works of art in which he was able to demonstrate this fact adorn the anteroom of what used to be his clinic at the Saltpétrière. A new feature of pathology in art has been taken up by a German. Dr. C. H. Stratz points out some curious symptoms of disease in types represented in works of art. He finds that Botticelli's "Venus," in the Uffizi at Florence, for instance, is suffering from consumption, and should not be riding across the sea in an open shell without clothing.

This presents a new and comparatively unworked field to the pathologist. Shall we call the new branch of science historical or artistic pathology?

Dr. Manges, Professor of Medicine at the New York Polyclinic.—At the last meeting of the Faculty, Dr. Morris Manges was chosen to fill the Chair of General Medicine left vacant by the death of Dr. Page.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

SMALLPOX FOR SIX MONTHS IN ENGLAND—SUICIDE OF A LEPER—FORGOTTEN FRACTURE OF THE SKULL—BRITISH RED CROSS SOCIETY—VARIATIONS IN LONDON WATER-SUPPLY ANALYSES—MASTER TOMMY ATKINS DOWN WITH SCARLATINA—SIR WM. MAC CORMAC TO GO TO SOUTH AFRICA—LABORATORY MEETINGS OF PATHOLOGICAL SOCIETY—COST OF PHYSICIANS' MOTOR CARS—OPENING OF LIVERPOOL SCHOOL OF TROPICAL MEDICINE—$3,500,000 FOR SANITARY HOMES IN LONDON—PROFESSOR SCHAEFER'S ORATION AT EDINBURGH—GAS-POISONING BY LEAKAGE FROM GASOLIER.

LONDON, November 5, 1899.

THE epidemic of smallpox at Hull, the chief seaport on the northeastern division of the English coast, which began last spring has been smouldering in a most astonishing manner. It was originally imported in the crew of a Portuguese vessel, and the first cases were of such a mild type, that a number of people were exposed before the nature of the disease was recognized. All infected cases were promptly isolated and a most rigid system of inspection established. Yet the number of individuals exposed must have been much greater than originally believed, for no less than 300 cases have now been notified since the outbreak six months ago. As 36 new cases were reported last week and the Sanitary Committee of the Council has resolved to add two additional blocks to the hospital and a medical officer and four supplementary nurses, it looks as if the end of the trouble was not yet in sight. The only redeeming feature is that the epidemic has been extremely mild in character.

A death of peculiar pathos, even to our much-worn sense of the tragic, has recently occurred. A man named Edwards committed suicide by throwing himself from the window of a poor-house infirmary. He had been a sailor, who after long residence abroad, some six years ago returned home in a well-developed stage of leprosy. The poor fellow had become well known to the medical students and visitors of London, as he had exhibited himself once a month at University College Hospital almost ever since his return, as their "stock" case of leprosy. It must, I think, have struck all of us with wonder who have seen these necessary, but pitiful, exhibitions of this pathological rarity, that more of the poor creatures do not choose this means of escape from the prospect of awful disfigurement and a lingering death. The jury mercifully returned a verdict of "suicide whilst of unsound mind." But put the soundest of our minds in his circumstances and we doubt if the result would differ much.

An interesting illustration of the way in which even severe injuries may not only be completely recovered from but totally forgotten, was afforded in the death of a dock-laborer at Southwark this week, upon whom, on account of the suddenness of his demise, an autopsy was ordered held by the coroner. On laying forward the scalp a depressed fracture was found running five inches along the vertex of the skull. None of the immediate relatives of the deceased appeared to be able to account for it, until a brother was found who remembered that twenty-five years before, the deceased had been trapped between two vans and rather severely injured. Fortunately the fracture was evidently of long standing and there was an obvious cause of death in the condition of the heart-valves. For an injury of that degree of severity to have left no symptoms whatever and to have been apparently entirely forgotten by all but one relative of the deceased is an interesting illustration of the recuperative powers of the human frame.

The British Red Cross Society is holding meetings for the purpose of raising funds for sending out medical men and trained nurses to the Cape. Its success, however, seems to be hampered by the charges, to which we alluded in a former letter, brought against the management of the Society by one of its founders, and especially by proposed absorption into the Medical Department of the War Office, thus making it a mere Government bureau. One of the chief sources of the strength of the Society in former years has been the direct reliance upon individual good feeling, its freedom from the numbing influences of red tape and the rapidity with which it could both raise money, despatch organizers, and secure supplies, either upon the spot, or by shipment, as the need of the case demanded, by its plentiful supply of cash subscriptions

The London County Council has at last very properly taken up the question of the systematic analysis of the London water-supply. As it stands at present analyses are made by Sir E. Frankland, on behalf of the Local Government Board, but only about once a month. The chemist of the County Council makes his reports daily, while the chemists employed by the companies themselves make their reports once a week. The variance between these three series is something extraordinary, those by the companies' own chemists being naturally far the most favorable to the company. A brief investigation let the cat out of the bag, as to this divergence, as it was found that the companies' chemist, were careful to draw the samples from the clear wells just beyond the filter-beds, while the other samples were taken from the mains in various parts of the city. The Council proposes to attempt a uniform examination by one single authority, and will suggest to the Local Government Board that they should take charge of this and that samples should be taken from various parts of London, without previous warning and at least once a day.

A whimsical commentary upon the youth of some British regiments is furnished by the fact that one company of a regiment, in garrison in a northern town, was prevented from leaving with the rest of their battalion for South Africa on account of a violent outbreak of scarlet fever among them, It will be remembered that much stress was laid upon the folly of sending regiments of mere boys to run the gauntlet of tropical diseases in the discussion at the late British Medical meeting. And certainly if young Master Atkins has made so little progress toward adult immunity as to fall a victim to scarlet fever, one can only wonder what he will do when he is exposed to cholera, the plague or malaria. It is interesting to note that the recommendations of medical men, in regard to

the much higher resisting-power of well-grown adults, has formed a basis of the present English army scheme. This, instead of allowing a comparatively small number of men to enlist for a minimum of 14 years or a maximum of 28 years, in the hope of keeping a small proportion of seasoned soldiers at the head of a huge ruck of raw lads, is now upon the basis of seven years' active service, followed by 14 in the reserve, in civil employment. The intention of this plan being, first, to pass a much larger proportion of the fighting strength of the community through the ranks, and in the second place to do the garrison and police work with the younger troops, and have the older seasoned men to fall back upon at once in case of hostilities upon a serious scale. The system has received its first practical test in the recent calling up and despatch of the reserves, and it has evoked nothing but praise for the quality of the sturdy, vigorous manhood which has responded to its country's call. Medically and physically the system is probably one of the best that has yet been devised, although perhaps from a purely physical point of view, in promoting the highest development of the mass of the community both as athletes and as soldiers, it is perhaps inferior to conscription.

No more striking illustration has yet been given of the strong hold, which even this little war has taken upon the feelings of the English people, than the announcement by the Under Secretary for War in the House of Commons last night, that Sir William MacCormac, President of the Royal College of Surgeons, had volunteered to go out with Sir Redvers Buller's command to South Africa. The announcement was received with cheers, and the secretary stated that the Government had accepted Sir William's generous offer, and that he would be provided with at least two civilian staff assistants. At the same time the enrolment of 52 medical men from civil practice in South Africa itself was announced, so that the shortage in the army medical service seems in a fair way to be made good.

The London Pathological Society has made a striking and interesting departure in its method of holding meeting during the coming year. Instead of meeting at a fixed place continuously like all other medical societies, one-third of its meetings will be held in the laboratories of its members either in research institutions or in colleges. So that instead of simply a written report with figures and a handful of specimens, a complete demonstration of any new results or processes can be made and verified and criticised at every step. The facts of this departure can hardly fail to be beneficial in every way, both as improving the quality of the original work done by the members and as affording them an opportunity for practically reporting progress and allowing the members to judge for themselves of the bearings of the work even before a complete and final conclusion has been reached. In order to render this interchange of views perfectly free and confidential, these meetings will be considered private sessions and none of the processes or results shown will be published without the special consent of the demonstrator. Its only injurious effect will be that of rendering a scientific body, which, like most of the London medical societies, already errs, to our Transatlantic eye, a little on the side of exclusiveness, practically a *mare clausum* to the outside profession whether home or foreign, and of course, journal reporters will be excluded from the meetings. However, this will probably be more than made up for by the improved quality of the work ultimately done and published.

A discussion of some practical interest has been going on in the columns of the *Lancet* in regard to the cost of motor cars for use in medical practice The popularity of these is rapidly increasing in England, apparently even more so than with us, and they are giving an amusing illustration of the well-known evolutionary law that an improved type tends first of all to exterminate its immediate predecessors and nearest rivals. Not only is the motor car on account of its cheapness, small stabling requirements and ability to be managed by the physician himself without the services of a coachman, replacing the horse on economical grounds, but by its more frequent presence on the streets is rendering the use of any but the dullest-spirited animal, unpleasant if not actually unsafe. A comparison of various makes appears to indicate that the expense per annum of a "petrol" motor car is about $180 a year, including repairs, interest upon money invested, fuel and license. This, of course, is barely half the expense of a single horse at city prices, and as it probably does the work of a pair of horses with their requirements of stable, coachman, etc., it would certainly represent a very decided financial saving, while to those who are of a mechanical turn of mind, its use probably gives quite as much pleasure as that of driving the living animal.

The Liverpool School of Tropical Medicine has just opened with a very small attendance, in spite of the distinction already won by it through its Sierra Leone Malaria expedition. This is attributed by the secretary in large measure to the same cause as that suggested in our last letter for the similar state of affairs in the London Post-Graduate Schools, *viz.*, the recall of numbers of army medical men and colonial officers to their posts. And, as at the Polyclinic, a number of these had actually entered for courses of instruction at the Liverpool School. A well-deserved compliment has been paid the school by the entrance for several of its special courses of Dr. Miyamoto, Professor of Medicine in the Imperial University of Tokio.

England evidently firmly intends to maintain the high position which, somewhat to her surprise, was accorded to her in the matter of a low death-rate from tuberculosis at the late Congress at Berlin. This was regarded as largely due to the relative absence of over-crowding, shown in the low average number of inmates per house, as compared with that in the continental countries. At its last session the great London County Council, probably one of the most enlightened and conscientious municipal governing bodies in the world, decided to devote no less than $3,500,000 to the destruction of various unsanitary tenements and the rebuilding of model homes for the same class of workmen. This is only one of a number of great sums which have been spent for the same purpose in the past ten years; and one of the smaller boroughs in the East End,

ment of nearly $1,500,000 in the erection of model cottages for laboring men.

The most interesting feature of the opening of the Edinburgh School last week was the address of Professor Schäfer, signalizing his assumption of the duties of the chair of Physiology in succession to the late Professor Rutherford. So great was the desire to hear the address that it had to be adjourned from the very large lecture hall of the department to the great central hall of the University itself, a thing unprecedented in the annals of the college. It is pleasant to see that Professor Schäfer can count upon such a cordial reception of his work in his new field, especially as it was at one time a little to be feared that the passing over of several strong local favorites in favor of a stranger and a Southron might have led to a little hard feeling. The brainy Scot is quite accustomed to descending upon the best positions that the South has to offer, but it is not often that the current sets in the opposite direction, although Lord Lister will be remembered as a notable exception to this rule.

The address in Medicine was delivered by Dr. John Willey in the enforced absence of Sir William Grainger Stewart, but the gratifying announcement was made that Sir William's health was almost completely restored and that it was only as a matter of extra precaution that he was advised not to resume his duties until the summer session.

A case has occurred of poisoning from the escape of illuminating gas by a method of leakage which, fortunately, we are little exposed to on the other side of the Atlantic. The sliding gasolier is a prime factor here in England, and as, of course, it involves the telescoping of one tube inside the other and the packing wears rapidly, a complete sealing of the joint is secured by the presence of a cup fastened to one of the segments, which is kept full of water, and this seals the joint "trap-fashion." The contrivance has one very serious defect and that is, that the water tends constantly to evaporate and unless much greater watchfulness than that possessed by the average householder, let alone the servants, is exercised the trap becomes dry and a leakage of gas occurs, especially when the tube is pulled down to its greatest length. This is all the more dangerous because the escape may be very slight and gradual so that the gas almost imperceptibly accumulates in the air. A nearly fatal case of poisoning from this cause has just been reported from Norwich and the very pertinent suggestion is made by several of the journals, that in future these cups should be filled with oil, or glycerin, or some other fluid which does not rapidly evaporate. A better method of reform would however, be the total abolition of the sliding gasolier, as the small additional convenience in varying the height of the chandelier is far more than counterbalanced by the great and humanly-speaking, uncontrollable risks.

The Suit for Malpractice against Dr. Robert E. Coy of Rockford, Ill., in which the plaintiff asked for $10,000 damages, was on November 1 dismissed, the plaintiff paying the costs. All of Coy's professional confrères were ready to endorse his conduct of the case.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Regular Meeting, Held October 17, 1899.

THE Chairman of the Section, DR. LOUIS FAUGERE BISHOP, in the Chair.

The first feature of the evening was some remarks from the Chairman on

THE RELATION OF THE PHYSICIAN TO THE STATE.

Dr. Bishop said in brief that the evening before just when sitting down to transcribe his address he had been disturbed by a patient whose case would serve as an introduction to his remarks, and to the proper subject of the evening. She was a young woman who had consulted him for the first time last July. She then presented symptoms of incipient tuberculosis, but in a very early stage. He had advised her to give up work and to go into the country for some time. This she did at that time, and rapidly improved. Her cough became very much less; her tendency to free perspiration, especially in the afternoon, which indicated a slight febrile condition disappeared, and she did not have any more night-sweats. She gained four pounds in weight. But at the end of eight weeks her funds were exhausted, and she was compelled to return to the city and to her occupation. She soon began here to have her old symptoms once more. They finally culminated in a pulmonary hemorrhage, and she was advised to return to the country, but she said simply that she could not because she had not the money. She was told that life depended on her going back, but that made no difference, she could not.

We know that such cases are practically always curable under proper treatment, and it is positively vexatious to be met by the money difficulty. A few dollars represents the difference in such cases between a slow, lingering, but inevitable death, and a long, perhaps happy, life.

Here is where the State can aid the physician in his work for the alleviation of human suffering. Here is where as physicians we have a right to demand such aid from the State. The State owes it to her citizens as much as she owes them other care. That to-night's meeting may serve the purpose of making this clear to the profession and to unite them in the effort to obtain this aid for the poor from the State is the object of the meeting, but this will be made clearer by others to follow. The paper that opened the discussion of the evening was read by DR. ALFRED MEYER, and was entitled

THE STATE CARE OF CONSUMPTIVES, WITH AN ACCOUNT OF THE MASSACHUSETTS STATE HOSPITAL FOR TUBERCULOSIS.

Dr. Meyer said in brief: "Few changes in medical thought are more striking than those which have come of late in the matter of the prognosis of phthisis. Formerly it was thought absolutely incurable. Laennec thought a cure possible sometimes after the cavity stage had been that of West Ham, is actually contemplating the invest-

reached. Niemeyer thought that death was the inevitable termination except if the disease followed pneumonia, when curiously enough he thought the prognosis was not so bad. Aretæus, Hippocrates, and Galen all thought that the outdoor treatment of tuberculosis did good. It is nearly fifty years ago now, since in Germany the curability of the disease was once more put forward. All this time there was proof of the curability of tuberculous processes in the post-mortem conditions which were found in lungs that had been affected by tuberculosis. Pessimism in the matter has now given place to a reasonable optimism and the treatment of the disease in sanatoria is considered always to do good. There is scarcely a country in Europe without sanatoria for the poor. Even in Japan two years ago a sanatorium was established. Massachusetts has begun the good work in this country. It opens up a possibility, a promising vista of great good for the tuberculous poor. She has set us an example as great in its way as that she set in the matter of slavery. A bill was introduced into the New York legislature last year appropriating $200,000 for a sanatorium for the tuberculous poor in this State in the Adirondacks. Unfortunately it did not become a law. Certain features which were objected to last year have been expunged and certain suggested improvements made, and it is hoped that it will pass the legislature this winter.

A few words about the sanatorium established by the State of Massachusetts may not be out of place. It is situated at Rutland near the exact center of population of the State. It consists of a number of separate wards, one story in height connected only by a corridor. The wards radiate from the administration building, which occupies the center as it were. It is under the care of both the allopathic and homeopathic practitioners. Certain features of the management are of general interest. Each patient has his own cuspidor, which is attended to very carefully. Paper handkerchiefs are used whenever the patients are out of the building and after use are enclosed in a self closing rubber pouch, somewhat like the old tobacco bags, and the handkerchiefs are burned. Paper napkins are used at the table. Special features of the institution and very popular ones are the winter camps in which patients live out of doors all day. The windows on the leeward side of the house are always kept open even in the coldest weather. The temperature of the wards in the winter time is scarcely ever above forty degrees Fahrenheit. At present there is but one nurse for each thirty-two patients. During the day and at night one nurse in the male and another in the female department are on duty. There are no male nurses. The administration realizes that this is an insufficient number of nurses, but their funds will not justify them in employing more.

A very commendable feature is the absolute separation of hopeless cases from those that are improving. If there is no improvement in from four to six weeks after entrance into the sanatorium the patient is discharged. The improvement is judged of by a lowering of the temperature, a lessening of the rapidity of the pulse, and an increasing weight and appetite. It is surprising what little coughing is heard in the institution. This has often been noticed before in hospitals of the same kind. During my stay there I seemed to be the only one who coughed. The average number of patients in the institution is about 400. The improvement is very marked.

This is what Massachusetts has done for the tuberculous, why should not New York do at least as much. One of the objections urged against the establishment of sanatoria for the tuberculous is that it savors too much of governmental paternalism. This sort of thing it is said should be left to private endeavor and individual benevolence. It does not come from these sources, however, and now that the tuberculous are being excluded more and more from general hospitals there is a crying need for special institutions. From the legal aspect it may be noted that all State constitutions provide for hospitals as well as for State prisons. It is a well-recognized principle that the State should care for its sick as well as for its criminal classes. The theoretical objections then may be waived as they have been in Massachusetts and great good will result. The practical objection is mainly money. This was formerly urged against the State care of the insane. How shortsighted such an objection was we are much better able to judge now that State hospitals for the insane have fully justified their existence. The decrease of consumption should not deter us but rather encourage us in this matter of founding sanatoria for the tuberculous poor. Ransom has shown by statistics that if consumption continues to decrease in England during the next thirty years as it has during the last fifty it will disappear. These statistics seem almost too favorable, but whatever can be done to shorten the interval before the disappearance of the disease will mean the saving of many precious lives and relief from a great deal of human suffering.

In discussion Dr. Flick said that it is the privilege of our generation to wipe out the great white plague that has carried off more people during the world's history than all other diseases combined. He then reviewed the movement with regard to the prevention of tuberculosis as it has developed in this country. The first discussion on this subject was the result of a paper read by himself in February, 1890. The result of this discussion was the establishment of the Rush Hospital for Consumptives, which still exists and is doing good work, though not as much as might have reasonably been expected. Since then discussions have taken place before most of the national societies. Thus far the main thing accomplished by the discussion has been the education of the public. In order that this may be more complete the medical profession must be a unit in the matter of the measures deemed necessary for the control of the disease and of the results to be obtained by them. In Europe only the rulers need to be educated in order to secure the foundation of sanatoria. Here in this country the whole sovereign people must be educated in order to accomplish a like result. Medical societies in every State then should take the matter up earnestly.

The State should supply sanatoria for incipient cases of tuberculosis, the Cities hospitals for advanced cases.

These will be of the greatest benefit to the well as well as to the sick. Government has assumed the responsibility for the health of the citizens. The constitution assures to every one the right to health and the pursuit of happiness. Danger from disease is the equivalent of other dangers, and the State has the duty to protect us.

How different the world would be if the "white plague" had been stamped out one hundred years ago. During this century some of the best of the human race in the heyday of their youth and the fulness of their energy have been taken off by it. People whose influence would have been incalculable. With reference to the reduction of the mortality from consumption in England, it must be remembered that England established special hospitals for consumptives a good many years ago, and that *pari passu* with the number of patients under treatment in the tuberculosis hospitals in England has been the reduction in the mortality from the disease. There are at present 10,000 beds in the consumptive hospitals in England. London has the lowest death-rate from consumption of any large city in the world. Forty years ago the mortality from this disease was very large. Curiously enough these hospitals were established not for the cure of the disease, but in order to furnish a place where consumptive patients might die in peace and under proper care. The humane idea has worked itself out into a great saving of life and of health in a quite unexpected, but very acceptable manner.

DR. VINCENT Y. BOWDITCH of Boston said we have the first State sanatorium for tuberculosis in Massachusetts and as the result of our experience with it, would be only too glad to have others share in the benefit. At first we thought that one of the difficulties to be encountered in a public sanatorium would be that refined patients, who were nevertheless poor, would not be satisfied to be under treatment in the wards of a hospital. The result has been very different from our anticipation. Patients, of the most deserving classes have come and the spirit of cheerfulness that reigns in the hospital wards is one of its most encouraging features. We did not secure enough money in our appropriation. Be sure that you do secure it here for it can be easily obtained, if asked for with the confidence that should be felt in this matter. One of the chief benefits of the sanatorium is its educational effect upon the community. Patients who go home improved in health, preach the gospel and practise of cleanliness, of abundant fresh air, and of good nourishing food to their friends and the amount of sanitary work that is done by the knowledge of proper precautions thus spread is simply incalculable. Our results for the first year have been eminently encouraging

DR. JOHN H. PRYOR of Buffalo stated that a great decrease in the mortality from consumption has been claimed to have taken place in England and also in New York, and it is said that the disease will disappear before long. I do not believe that the statistics of its decrease are correct, or that it ever will disappear. In certain years there has been a great decrease, but the general death-rate has also been very much less in those years. Last year there was an actual increase of 339 deaths from the disease in this State. A much more than proportionate increase to that of the population. This year in the first eight months there was an increase of 650 deaths, and if the death-rate continues for the next three months as it has for the past nine, and there is no reason why it should not, there will be more than 1000 more deaths this year than last. This is the largest increase recorded.

Under present circumstances, the poor, instead of having been benefited by the discovery of the tubercle bacillus and of its contagiousness, have rather been hurt. Their condition has been rendered more pitiable. Hospitals do not want to receive them, or at least do not want to keep them for long periods, and their presence in a community is generally considered undesirable. As it is now, the poor die because they are poor and for no other reason, for we have found that the treatment of tuberculosis can be carried on with reasonable success under favorable conditions.

Unfortunately there is no consensus of opinion among medical men, and county and state medical societies do not lend the weight of their influence to help out the poor under present circumstances. The present death-rate from consumption, I do not hesitate to say, is nothing less than a disgrace to the medical profession. Action on the part of medical men and of all medical bodies is greatly needed at present. The State would actually save money by establishing sanatoria for consumptives, for thousands of young people who are now yearly carried off would add many times more to her wealth than the amount of money that could possibly be spent in taking care of them, until they are well enough to resume their occupations. Sanatoria near home and sanatorium treatment here will do more good than at a distance, as in Colorado. More patients will remain well after their discharge from the sanatorium if the treatment has been carried on in a climate not unlike that in which they are to live afterwards.

DR. BRUSH of Brooklyn, stated that the annual loss now entailed by the deaths of consumption exceeds the whole cost of the State government. The State undoubtedly has the duty to protect her citizens in this matter, if she has the right to spend money in quarantining against contagious diseases liable to be introduced. The effective work against tuberculosis can be carried out more successfully than with regard to other diseases. As it is now the tenements breed the disease and the dwellers on the avenue suffer. As a business proposition then it would pay the State to invest in sanatoria for the poor.

DR. WM. H. THOMPSON said that the great danger in tuberculosis is not so much from the tubercle bacilli as from mixed infections. The alliance with bacteria that cause pus produces destructive ravages in the lungs. Some years ago surgeons opened the abdomen by mistake in several occasions when patients were suffering from tuberculosis of the peritoneum. To their surprise their patients got better after the closure of the abdominal wound. Somehow the exposure to air caused a retrogression of the tuberculous process. Some time since, a

surgeon at St. Mary's Hospital, London, pointed out the fact that the best treatment for pyemia was what he called hyperventilation, that is, patients were placed in rooms at the top of the house and in rain or fog or wintry weather as well as on fair days all the windows were kept open. The results secured by this method of treatment were excellent. The same organisms that cause secondary infection in tuberculosis are at work in pyemia, hence the good results that might be expected from the open-air treatment which can be best carried out in sanatoria.

MR. EDWARD T. DEVINE, General Secretary of the Charity Society, said that he hoped that a new regulation which his society had induced the council to introduce into the building laws would lessen the amount of tuberculosis among the poor in the tenement-houses. At present light-shafts in tenement-houses need not be any more than two feet and a half in width. The requirements should be that they should be at least six feet in width and this change has been proposed and the area of the light-shaft required to be fifty square feet.

DR. LEE K. FRANKEL, Manager of the United Hebrew Charities, said that his Society had never allowed other State institutions to take care of Hebrews, but had always insisted on taking care of them itself. They must now confess, however, that they were unable to cope with the problem presented to them by tuberculosis among the poor. And so they joined with others in asking for State aid.

DR. DANIEL LEWIS, President of the State Board of Health, advised going slow in the matter. Ill-directed legislation was often worse than none. The first thing that should be done was the erection of hospitals for the treatment of severe cases in order to prevent infection. As president of a State board of health he felt the necessity for this very much, and felt that the present movement asking for legislation for the care of incipient tuberculosis suggested a beginning at the wrong end of the line.

DR. S. A. KNOPF said that three kinds of hospitals for tuberculosis were needed: reception hospitals in the city, hospitals for the treatment of incurable cases of tuberculosis not far distant from the city, and finally sanatoria for the treatment of incipient tuberculosis in favorably situated localities. There was often considerable talk of the danger brought into a neighborhood by the presence of one of these hospitals. As a matter of fact, however, the educational influence of sanatoria caused the death-rate in their vicinity to grow less. This had occurred at Görbersdorf and at Falkenstein in Germany.

DR. NAMMACK introduced a resolution to the following effect: WHEREAS, tuberculosis is curable and private enterprise is not in a position to provide the necessary means for the erection of sanatoria for its successful treatment. *Resolved*, This section proclaims its approval of sanatoria for pulmonary tuberculosis and recommend that the New York Academy of Medicine take some formal action in order to have the Legislature pass a law providing for the erection and maintenance of such sanatoria.

CIRCULAR OF INFORMATION.

RULES AND REGULATIONS OF THE INTERNATIONAL CONGRESS.

I. THE Thirteenth International Congress of Medicine will open at Paris on August 2, 1900, and will close on August 9th. Its object is of an exclusively scientific nature. II. Membership will be granted: (1) To all doctors of medicine who apply for membership. (2) To the representatives of science who shall be presented by the French Executive Committee or by the Foreign National Committees. III. Members will receive their cards on forwarding the sum of 25 francs (£1) to be paid to the Treasurer General of the Congress. This card will be required for admittance, and to secure for the members the advantages reserved for them. The Foreign Committees may receive the adhesions of members of their respective nationalities. The committees will hand over the payments received to the French Secretary General, who will supply them in turn with members' cards in number corresponding to the payments. IV. In forwarding payments to the treasurer members should put their name, profession, and address plainly and legibly, and subjoin their visiting card. V. Among other advantages, members will be entitled to receive a digest of the proceedings of the Congress, and the printed report of the section to which the member belongs.[1] VI. The Congress will be divided into the following sections:

1st. Biological Sciences.—(1) Descriptive and comparative anatomy. (2) Histology; embryology and teratology. (3) Physiology; biological physics and chemistry.

2d. Medical Sciences.—(1) General pathology and experimental pathology. (2) Bacteriology; parasitology. (3) Pathological anatomy. (4) Internal pathology. (5) Hygiene and medical pathology of infancy. (6) Therapeutics and pharmacology. (7) Neuropathology. (8) Psychiatry. (9) Dermatology and syphilography.

3d. Surgical Sciences.—(1) General surgery. (2) Surgery of infancy. (3) Urinary surgery. (4) Ophthalmology. (5) Laryngology; rhinology. (6) Otology. (7) Stomatology.

4th. Obstetrics and Gynecology.—(1) Obstetrics. (2) Gynecology.

5th. Public Medicine.—(1) Legal medicine. (2) Military medicine and surgery; naval medicine; colonial medicine.

VII. An executive committee and an organizing committee will be charged with the labors of preparing and working the Congress. VIII. The Congress will sit every day, whether in the form of general assembles or of meetings of each section. IX. Two general assemblies will be held. The first will take place on the opening day of the Congress. The second will be held on one of the ensuing days. X. The first general assembly will elect the honorary presidents of the Congress. XI. The speeches and addresses, together with the voting ruled by the standing orders, will occupy the entire time of general as-

[1] Communications respecting the delivery of these reports to members to be addressed to M. Masson, publisher of the proceedings of the Congress, boulevard St. Germain, 120, Paris.

semblies. Those members will alone speak who have been appointed or invited by the executive committee. XII. All proposals relative to the course or nature of the proceedings of the Congress should be notified to the executive committee before May 1, 1900. The committee will decide in what measure these proposals shall be countenanced. XIII. Each sectional committee shall draw up its own working program (papers to be read, discussions on the subjects proposed, miscellaneous communications). XIV. The speeches delivered at the general assemblies and the papers read before the sections will be published in the record of the proceedings of the Congress; respecting the miscellaneous communications and the discussions, the Executive Committee reserves full right of discrimination. Each communication will be limited as to time to fifteen minutes, and the speakers who take part in the discussion will be timed to five minutes. XV. The papers, communications, and record of the discussions must be lodged on the very day with the secretary of the section. XVI. The French language is adopted as the official language by the Congress in all international relations. In the general assemblies, likewise in the sectional meetings, the German, English, and French languages may be employed. XVII. All matters relating to the proceeding of the sections, questions submitted for discussion, etc., to be laid before the president of the committee of the section. Matters concerning the general organization, business of the Congress, etc., to be referred to the secretary general of the Congress. XVIII. The second general assembly will meet to determine where the next Congress will be held and to elect the bureau.

SECTIONS.[1]

Biological Sciences. A. Section of Descriptive and Comparative Anatomy.—President, M. Milne-Edwards.[2]

a. Comparative Anatomy. — Vice-presidents, De Lagaze-Duthiers, Perrier, Filhol, Lavocat; secretary, Auguste Pettit, rue Saint-André-des-Arts, 60, Paris. Papers: (1) "Modifications of the Organs of Sense Brought about by Darkness," by Armand Viré, Paris. (2) "The Pithecanthropus," by Dubois, Leyden. (3) "Development of Some Lemurs," by Hubrecht, Leyden. (4) "Muscular Anomalies," by Ledouble, Tours. (5) "The Notochord," by Van Beneden, Liege.

b. Descriptive Anatomy.—Vice-presidents, Farabeuf, Paulet, Poirier; secretary, Rieffel, rue de l'École-de-Médecine, 7, Paris. Papers: (1) "Topography of the Brain," by Waldeyer, Berlin. (2) "Brain Centers of Association and Projection," by Debierre, Lille. (3) "The Ascending Passages of the Lateral Cord of the Spinal Marrow," by Van Gehuchten, Louvain. (4) "On Some Homologies of the Genital Organs," by Romiti, Pisa. (5) "Homologies of the Arteries of the Members," by Salvi, Pisa. (6) "The Suprarenal Capsules." By Valenti, Botogna; and Auguste Pettit, Paris.

[1] Members of the Congress who desire to put their name down for a communication or take part in the discussion of one of the papers proposed are requested to apply to the secretary of the section.

[2] Authors whose names bear no reference attached are from Paris.

b. Section of Histology and Embryology.—Honorary presidents, Ranvier and Balbiani; president, Mathias Duval; vice-presidents, J. Chatin and Henneguy; secretaries, Retterer and Loisel, rue de l'École-de-Médicine, 15, Paris. Questions Proposed for Particular Treatment: (1) Bronchial Derivatives. (2) Spectroscopy and Microspectroscopy in General Anatomy. (3) Functional Differentiation of Protoplasm. (4) Origin and Evolution of Leucocytes in the Animal Series. (5) The New Ideas Regarding the Histology of the Nervous System. (6) Chromatolysis. The Committee of the Section of Histology and Embryology will have rooms at their disposal and provide microscopes for the examination of preparations.

c. Section of Physiology, and Biological Physics and Chemistry. — President, Chauveau; vice-presidents, Marey, Armand Gautier, and d'Arsonval; secretary general, Dastre, á la Sorbonne, Paris; Secretaries, Gley, rue Monsieur-le-Prince, 14, Paris; Weiss, avenue Jules-Janin, 20, Paris. The Committee of the Section of Physiology do not propose any definite subjects for presentment in papers. The sittings will be given up to experimental demonstrations and communications upon subjects of a physiological interest, at the choice of the members.

Medical Sciences. (*a*) *Section of General Pathology and Experimental Pathology.*—Honorary presidents, Chauveau and Poutain; president, Bouchard; vice-presidents, Chantemesse and Langereaux; secretaries, Charrin, avenue de l'Opéra, 11, Paris; Roger, rue Perrault, 4, Paris. Questions proposed for particular treatment: (*A*) On the Condition of the Organism and the Modifications of That Condition with Relation to Infection and to Natural or Acquired Immunity. (1) On the Modifications of Humors in Infectious Diseases. (*a*) Application of Sera of the Blood to Therapeutics. (*b*) The Property of Agglutination and Its Relation to the Other Properties Acquired by the Humors. (2) On the Sources of Immunity in the Normal Organism. (3) On the Origin of Leucocytosis. (4) On the Organs Destructive of Microbes and Toxins. (5) Action of Toxins on the Nervous System. (6) Tropic Repercussion of a Nervous Origin in Infectious Diseases. (7) Pathogeny of Tetanic Contractures. (*b*) On Fever. (*c*) On Hereditary and Innate Characters. (1) Developmental anomalies and Conditions of Morbid Predispositions. (2) Influence of the Diseases of the Mother on the Nutrition, the Functional Activity and the Lesions of the Child. (*d*) The Diabetic. —Nutrition of the Diabetic. (*e*) Extrabuccal Alimentation. (*f*) Use of Röntgen-rays in Medical Semeiology. (*g*) Auto-intoxication.

(*b*) *Section of Bacteriology and Parasitology.*—President, Duclaux; vice-presidents, Arloing, Lyons; Laveran; secretary, R. Blanchard, boulevard Saint-Germain, 226, Paris. Papers: (1) "Tuberculosis," by Behring, Berlin. (2) "Immunity," by Büchner, Munchen; and Metchnikoff, Paris. (3) "Toxins and Antitoxins," by Ehrlich, Berlin; and Roux, Paris. (4) "Paludism," by Laveran, Paris; Danilevsky, Grassi, Rome. (5) "Parasites of Cancer," by Borrell, Paris.

(*c*) *Section of Pathological Anatomy.* President, Cornil; vice-presidents, Coyne, Bordeaux, and J. Renaut, Lyons; secretary, Letulle, rue de Magdebourg, 7, Paris. Papers: (1) "Histogeney of Epitheliomata," by Hlava (Prague), Fabre-Domergue, Paris; and Podvissotski, Kiev. (2) "Rôle of the Fixed Cells in Inflammation," by Baumgarten, Tubingen; Nikiforof, Moscow; and René Marie, Paris. (3) "Experimental Reparation of the Tissues," by Denys, Louvain; Ziegler, Freiburg and Carnot, Paris. (4) "Rôle of the Neuroglia in the Evolution of Inflammations and Tumors," by Weigert, Frankfurt; Marinesco, Bucharest; and Philippe, Paris. (5) "The White Globules of the Blood in Their Various Morbid Conditions," by Ehrlich, Berlin; and Jolly, Paris. (6) "Resistance of the Red Globules in Their Normal and Pathological States," by Hamburger, Utrecht; Hedin, Lund, Sweden; and Vaquez, Paris.

(*d*) *Section of Internal Pathology* (*General Medicine*).—President, Potain; vice-presidents, Dieulafoy, and Grasset, Montpellier; secretaries, Rendu, 28, rue de l'Université, Paris, and Widal, 155, boulevard Haussmann, Paris. Papers: (1) "Pathogeny of Gout," by Legendre, Paris; Ebstein, Gottingen; Sir Dyce Duckworth, London; and Kolisch, Vienna. (2) "Insufficiency of the Kidneys," by Achard, Paris; Laache, Christiania; Palinof, Moscow. (3) "Muco-Membranous Enteritis," by Ewald, Berlin; Mathieu, Paris; Nothnagel, Vienna; Revilliod, Geneva. (4) "Acute Edema of the Lungs," by Sirotonine, St. Petersburg; Von Basch, Vienna; Masius, Liege; Teissier, Lyons. (5) "Gastric Ulcerations," by Bozzolo, Turin; Dieulafoy, Paris.

(*e*) *Section of Medicine of Infancy.* Honorary president, Bergeron; president, Grancher; vice-presidents, Cadet de Gassicourt and Simon; secretary, Marfan, rue de la Boëtie, 30, Paris. Papers: (1) "Artificial Lactation, and in Particular the Use of Sterilized Milk," by Jacobi, New York; Johannessen, Christiania; Heubner, Berlin; Monti, Vienna; Variot, Paris. (2) "Gastro-intestinal Infections and Intoxications of Earliest Infancy," by Epstein, Prague; Escherich, Gratz; Baginski, Berlin; F. Fede, Naples; Martinez Vargas, Barcelona; Marfan, Paris. (3) "Infantile Tuberculosis," by d'Espine, Geneva; Hutinel, Paris; Richardière Paris; Moussous, Bordeaux. (4) "Acute Nodes Tubercular Meningitis," by Mya, Florence; Concetti Rome; Netter, Paris; Rauchfuss, St. Petersburg. Besides those questions which will form the subjects of papers, the Committee of the Section of Medicine of Infancy draws attention to the following questions: "Antidiphtheric Serotherapie;" "Infantile Rheumatism and Its Connection with the Infections of the Heart and Chorea;" "Alcoholism of Children;" "Constipation;" "Diseases of the Thymus."

(*f*) *Section of Therapeutics, Pharmacology, and Materia Medica.*—President, Landouzy; secretary, Gilbert, rue de Rome, 27, Paris. *I. Therapeutics.* Vice-president, Bucquoy; secretary, Gilbert, 27, rue de Rome, Paris. Papers: (1) "Treatment of Biliary Lithiasis," by Naunyn, Strasburg; Gilbert, Paris; and Fournier, Paris. (2) "Indications and Counter Indications of Blood-letting," by Baginsky, Berlin; Hayem, Paris. (3) "On Saline Injections in Therapeutics," by Landouzy, Paris. (4) "Should Fever Be Combated?" by Stokvis, Amsterdam; Lépine, Lyons. *II. Pharmacology.* Vice-president, Pouchet; secretary, Chassevant, rue Gay-Lussac, 32, Paris. Papers: (1) "Medicinal Associations in Therapeutics; Their Advantages; Their Disadvantages." (2) "Physiological and Therapeutic Action of Digitalis and Its Active Principles," by T. Lauder Brunton, London; Grocco, Florence. (3) "Mechanism of the Physiological and Therapeutic Action of Diuretic Medicines," by Tchebinof, Moscow; and Renaut, Lyons. *III. Materia Medica.* Vice-president, Planchon; secretary, Chassevant, rue Gay-Lussac, 32, Paris. Papers: (1) "Comparison Between the Therapeutic Action of Vegetable Pharmaceutical Preparations and Those of Their Immediate Active Principles." (2) "Present State of Our Knowledge Regarding the Active Principle of Digitalis," by Van Aubel, Liège. (3) "State of Our Knowledge Regarding the Various Species of Solanum," by Thoms, Berlin. (4) "Study on the Deterioration of Medicines Through Oxydation," by Bourquelot, Paris.

(*g*) *Section of Neurology.*—President, Raymond; vice-presidents, Brissaud, Dejerine, Grasset, Montepellier; Pitres, Bordeaux; secretary, P. Marie, 3, rue Cambacères, Paris. Papers: (1) "On the Centers of Projection and of Association in the Human Brain," by Flechsig, Leipzig; Hitzig, Halle; Von Monakow, Zürich. (2) "On the Nature and Canalization of Tendinous Reflexes," by Jendrassik, Budapest; C. S. Sherrington, Liverpool. (3) "Nature and Treatment of Acute Myelitis," by von Leyden, Berlin; Marinesco, Bucharest; Crocq, Brussels. (4) "Diagnosis of Organic Hemiplegia with Hysteric Hemiplegia," by Roth, Moscow; Ferrier, London. (5) "On Non-tabetic Lesions of the Posterior Branches of the Medulla," by Bruce, Edinburgh; Hómen, Helsingfors. (6) "On Various Points in the Study of Aphasia," by Tamburini, Reggio; Pick, Prague.

(*h*) *Section of Psychiatry.*—President, Magnan; vice-presidents, Joffroy, Gilbert Ballet; Pierret, Lyons; and Culerre, Laroche-sur-Yon; secretary, Ant Ritti, Asile de Charenton, Seine, France. Papers: (1) *Mental Pathology.*—"Psychoses of Puberty," by Ziehen, Jena; Marro, Turin; J. Voisin, Paris. (2) *Pathological Anatomy.*—"Pathological Anatomy of Idiocy," by G. E. Shuttleworth and Fletcher Beach, London; Mierzejewski, St. Petersburg; Bourneville, Paris. (3) *Therapeutics.*—"On the Confinement to Bed in the Treatment of Acute Forms of Insanity and on the Modifications that it Might Entail in the Establishment of Houses for the Insane," by Clemens Neisser, Leubus; Korsakof, Moscow; Morel, Mons. (4) *Legal Medicine.*—"Sexual Perversion with Obsession and the Impulses from the Medico-legal Point of View," by von Krafft-Ebing, Vienna; Morselli, Genoa; Paul Garnier, Paris.

(*i*) *Section of Dermatology and Syphilography.*—President, Besnier; secretary, G. Thibierge, 7, rue de Surènes, Paris. Papers: (*a*) *Dermatology.*—(1) "Para-

sitic Origin of Eczemas," by Kaposi, Vienna; Unna, Hamburg; Jadassohn, Bern; J. Galloway, London; Brocq, assisted by Bodin, Rennes; and Veillon, Paris. (2) "Tuberculides," by Boeck, Christiania; T. Colcott Fox, London; Campana, Rome; G. Riehl, Leipzig; J. Darier, Paris. (3) "Peladæ," by Malcolm A. Morris, London; Lassar, Berlin; Mibelli, Parma; Pavlof, St. Petersburg; Sabouraud, Paris. (4) "Leucoplasiæ," by A. Behrend, Berlin; J. J. Pringle, London; Perrin, Marseilles. (*b*) *Syphilography.*—(1) "Syphilis and Allied Infections," by Neisser, Breslau; D. Bulkley, New York; Ducrey, Pisa; Hallopeau, Paris. (2) "Transmission in the Hereditary Syphilitic," by J. Hutchinson, London; Tarnovsky, St. Petersburg; Finger, Vienna; L. Jullien, Paris. (3) "Causes of Generalized Infections in Blennorrhagia," by W. Taylor, New York; Lesser, Berlin; Tommasoli, Palermo; J. E. Lane, London; Balzer, Paris.

Surgical Sciences. (*a*) *Section on General Surgery.*—President, Tillaux; vice-presidents, Ollier and Léon Labb; secretary, Walther, 21, boulevard Haussmann, Paris. Papers: (1) "Surgery of the Pancreas," by Ceccherelli, Parma; A. W. Mayo Robson, Leeds; J. Boeckel, Strassburg. (2) "Radiography in the Examination of Fractures and of Luxations," by Ashurst, Philadelphia; Bergmann, Berlin; Maunoury, Chartres. (3) "Treatment of Tainted Wounds," by Bobrof, Moscow; Bloch, Copenhagen; Lejars, Paris. (4) "Intestinal and Gastro-intestinal Anastomoses," by Roux, Lausanne; Kraske, Freiburg; Chaput, Paris.

(*b*) *Section of Surgery of Infancy.*—President, Lannelongue; vice-presidents, Kirmisson and Piéchaud, Bordeaux; secretaries, A. Broca, 5, rue de l'Université, Paris; and Villemin, 58, rue Notre-Dame-des-Champs, Paris. Papers: (*1*) *Treatment of Congenital Luxations of the Hip.*—(*a*) "Treatment by Sanguinary Operations," by Hoffa, Wurzburg. (*b*) "Treatment by Non-sanguinary Methods," by Lorenz, Vienna. (*c*) "General Survey," by Kirmisson, Paris. (*2*) *Treatment of Pott's Disease.*—(*a*) "Treatment During the Initial Phase and During that in Which the Gibbosity is in Course of Formation," by Soubbotine, St. Petersburg. (*b*) "Treatment During the Phase in Which the Gibbosity is Completed," by Bradford, Boston, U. S. A.) (*3*) "*Therapeutic Indication of Appendicitis,*" by F. Treves, London; Roux, Lausanne; and Jalaguier, Paris.

(*c*) *Section of Urinary Surgery.*—President, Guyon; vice-presidents, Albarran and Pousson, Bordeaux; secretary, Desnos, 31, rue de Rome, Paris. Papers: (1) "Conservative Operations in Retention of the Kidneys," by Kuster, Marburg; Christian Fenger, Chicago; Bazy, Paris. (2) "Value of Surgical Intervention in Urinary Tuberculosis," by Saxtorph, Copenhagen; Hogge, Liège; Pousson, Bordeaux. (3) "Remote Results of Operational Treatment of Prostatic Hypertrophy," by W. White, Philadelphia; Von Frisch, Vienna; Legueu, Paris. (4) "Remote Results of Sanguinary Intervention in Urethrostenosis," by Reg. Harrisson, London; Mariachess, Odessa; Albabran, Paris.

(*d*) *Section of Ophthalmology.*—President, Panas; vice-presidents, Javal; and Gayet, Lyons; secretary general, Parent, 26, avenue de l'Opéra, Paris; assistant secretaries, Chevalereau and Rochon Duvigneaud. Papers: (1) "Optic Neuritides of an Infectious and of a Toxic Origin," by Bellarminoff, St. Petersburg; Nuel, Liège; Uhthoff, Breslau. (2) "Cortical Center of Vision," by Bernheimer, Vienna; Angelucci, Palermo; Henschen, Upsala. (3) "Comparative Value of Enucleation and of the Operations Suggested to Replace It," by Pfluger, Berne; Snellen, Utrecht; R. H. Swanzy, Dublin; de Schweinitz, Philadelphia.

(*e*) *Section of Laryngology and Rhinology.*—President, Gouguenheim; secretary, Lermoyez, 20 bis, rue La Boëtie, Paris. Papers: (1) "Pathogeny and Treatment of Ethmoiditis Suppurata," by Bosworth, New York; Hajek, Vienna; Schoeffer, Bremen. (2) "Spasmodic Rhinitides and Their Consequences," by Jacobsen, St. Petersburg; Masini, Genoa. (3) "Anosmia and Its Treatment," by Onodi, Budapest; Heymann, Berlin. (4) "Indications and Technique of Thyrotomy," by E. Semon, London; Schmeigelow, Copenhagen; Goris, Brussels. (5) "Vocal Nodules," by Krauss, Berlin; Capart, Brussels; Chiari, Vienna. (6) "Diagnosis of Cancer of the Larynx," by B. Fraenkel, Berlin; M. Schmidt, Frankfurt-am-Main.

(*f*) *Section of Otology.*—President, Gellé; secretary, Castex, avenue de Messine, 30, Paris. Papers: (1) "Surgical Treatment of Otic Sclerosis," by Siebenmann, Bâle; Botey, Barcelona. (2) "Pyoæmia Otitis," by Dundas Grant, London; Brieger, Breslau. (3) "Causes and Treatment of Ménière's Vertigo," by von Stein, Moscow; Moll, Arnheim; Pritchard, London. (4) "Acoustic Exercises for Deafness," by Urbantschitsch, Vienna; Rohrer, Zürich. (5) "Toxic Labyrinthitis," by J. Gradenigo, Turin. (6) "Acoustic Notations. Project of Unification," by Hartmann, Berlin; Schiffers, Liège.

(*g*) *Section of Stomatology.*—President, Pickiewicz; vice-presidents, Cruet and Gaillard; secretary, Ferrier, 39, rue Boissy-d'Anglas, Paris. Questions: (1) "The Intervention of Therapeutics in Anomalies of Position and Direction of the Teeth." (2) "Immediate Prosthesis in Its Applications to the Surgery of the Face." (3) "Influence of the Affections of the Mouth and of the Teeth on the Other Organs and on the General Systems." (4) "Choice of Antiseptics in the Treatment of Caries of the Teeth." (5) "Treatment of Alveolo-dental pyorrhea."

Obstetrics and Gynecology. (*a*) *Section of Obstetrics.*—President, Pinard; vice-presidents, Budin and Alph. Herrgott, Nancy; secretaries, A. Barr, 122, rue de la Boëtie, Paris, and Champetier de Ribes, 28, rue de l'Université, Paris. Papers: (1) "Etiology and Nature of Puerperal Infections," by Doleris, Paris; Pestalozza, Florence; Menge and Kroenig, Leipzig. (2) "On the Treatment of the Apparent Death of the New-born Child," by Ribemont-Dessaignes, Paris; F. H. Champneys, London; Fr. Schultze, Jena. (3) "Application of Radiography to Obstetrics."

(*b*) *Section of Gynecology.*—President, Terrier; vice-president, Pozzi; secretary, Hartmann, place Males-

herbes, 4, Paris. Papers: (1) "Surgical Treatment of Cancer of the Uterus," by Richelot, Paris; Dimitri de Ott, St. Petersburg; Montgomery Baldy, Philadelphia. (2) "On Cervical Metritides," by Pozzi, Paris; Döderlein, Tübingen.

(*a*) *Section of Legal Medicine.*—President, Brouardel; vice-presidents, Benoit, E. Demange, Lacassagne, Lyons; secretary-general, Motet, rue de Charonne, 161, Paris; assistant-secretary, Thoinot. Papers: (1) "Putrefaction in Its Relation to Docimasia Pulmonum," by Descoust and Bordas, Paris. (2) "Ocular Putrefaction as a Means of Determining the Time of Death," by Descoust, Paris. (3) "On the Burning of Bodies with Criminal Intention," by Ogier, Paris. (4) "Accidental Death by Electricity," by d'Arsonval and Bordas, Paris. (5) "Medico-legal Tests and Their Importance in View of the Accidents That may happen from the Habitual Use of Foods and Drinks Whose Preservation is Ensured through Chemical Agents (Borax, Salycilic Acid, Formol, etc.)," by Brouardel and Pouchet, Paris. (6) "Valvular Lesions Due to Contusion of the Parietes of the Chest," by Castiaux, Lille; Laugier, Paris. (7) "Action of the New Smokeless Powders on the Clothes and on the Skin," by Thoinot, Vielle, Paris. (8) "The Illegal Practice of Magnetism by Unqualified Persons," by Gilles de la Tourette, Rocher, Paris.

(*b*) *Section of Military Surgery and Medicine.*—President, Dujardin-Beaumetz; vice-president, Cunéo; secretary-general, Catteau, Ministère de la Guerre, Paris; assistant secretaries, Dziewonski and Alvernhe. Papers: (1) "On the Lesions Produced by Bullets of Small Caliber (of Six Millim. or Under)," by Habart, Austria; Lagarde, United States. (2) "On the Lesions Produced by Projectiles in Present Use in Artillery," by Demosthene, Roumania; Geissler, Germany. (3) "On the Rule for the Immediate Treatment of Fractures Produced by Gun-shot at the Ambulance or at the Field Hospital," by Bischer, Switzerland. (4) "The Subsection Desires That Those Doctors Who have taken Part in the Colonial Expeditionary Wars of the Last Ten Years should Describe, from the Experience of Their Practice, What was the Treatment of the Wounded, and to draw Some General Conclusions." (5) "Etiology and Prophylaxis of Typhoid Fever in the Army on Field Service," by Vincent, Paris. (6) "Etiology and Prophylaxis of Dysentery in the Army on Field Service," by Antony, Paris; and Simonin, Paris. (7) "Prophylaxis of Syphilis in the Army," by Ferrier, Paris. (8) "On Extemporé Means of Purifying the Water," by Lapasset, Paris. (9) "On Tropical Phagedenism," by Le Dantec, Bordeaux. (10) "Care of the Wounded to Be Given on Board Ship During and After Action: Transport of the Wounded. Means of Transport, First Dressing. Emergency Cases," by Fontan. (11) "Hospital Ships in Colonial Expeditions," by Burot. (12) "Plague. Bacteriology, Symptomatology, Serotherapy, Measures of Prophylaxis and Therapeutics," by Simon and Yersin. (13) "Tetanus in Hot Climates; Its Prophylaxis," by Calmette, Lille. (14) "Etiology and Prophylaxis of Bilious Hemoglobinuric Fever," by Firket, Liège.

REVIEWS.

A Text-Book of the Diseases of the Nose and Throat. By D. Braden Kyle, M.D., Clinical Professor of Laryngology and Rhinology in Jefferson Medical College; Consulting Laryngologist, Rhinologist, and Otologist to St. Agnes' Hospital, Philadelphia. Illustrated. Philadelphia: W. B. Saunders, 1899.

The author's aim to present to the reader the subject of diseases of the nose and throat in as concise a manner as is compatible with clearness has resulted in the production of a volume which as to press-work and general arrangement of the matter is admirable. The order of the chapters is somewhat different from that of many of the other text-books on this subject, as the plan has been to classify the diseases according to pathological alterations caused by them. This has resulted in some repetition, while on the other hand the advantage of ready reference is offered, and the reader finds at once, on turning to a certain subject, the matter desired, under the corresponding heading. The illustrations have evidently been prepared with particular care, many of the lithographs and original drawings having been made from specimens prepared by the author in his own laboratory, or from cases under his own immediate observation. Some of the anatomical cuts are composite, being made from a series of other illustrations together with original specimens.

The author's treatment of the subject is lucid, concise, and, generally speaking, complete. A number of minor omissions, however, appear on close inspection. Practically no mention is made of the use of the suprarenal capsule in nasal disease, and leptothrix amygdalitis is treated cursorily, especially as to symptomatology and treatment, no mention being made of reflex cough or of treatment by expression. In the chapter on the accessory sinuses, admirable in many respects, the operative procedures of Jansen, Czerny, and Nebringer are passed over in silence. No mention is made of the osteoplastic opening of the frontal sinus, after Golovine, which is, without much doubt, the method of election, in certain cases. It is also to be regretted that no chapter on affections of the trachea appears in the work, the more so, as symptoms referable to that organ so frequently accompany, or are induced by, laryngeal or nasal disease. The author, indeed, mentions the tracheitis complicating hyperplastic rhinitis, and laryngo-trachelo-ozena, but a complete discussion of this subject is not presented.

For the student Kyle's text-book is particularly well suited; the chapters on anatomy and physiology, no examinations and illumination and on diagnosis being especially thorough and copiously illustrated. The practical application of transillumination is described in extenso in the section devoted to diseases of the accessory cavities.

Die Mischgeschwueltse (Mixed Tumors). Von Dr. M. Wilms, Docent für Chirurgie in Leipzic. Heft 1: "Die Mischgeschwülste der Niere" (Mixed Tumors of the Kidney). Leipzig: Arthur Georgi, 1899.

We have read with interest this monograph on "mixed tumors" of the kidney. The author also intends to pub-

lish the results of his examinations in the class of tumors in other regions of the body, taking up the uterus and parotid tumors in succeeding monographs. The present work is devoted principally to the finer histology of the "mixed tumors" of the kidney, with the author's view as to their mode of origin. These tumors are all congenital in nature and are mostly discovered in the first three years of life. They always contain a variety of tissues, differing in this respect from the simple malignant kidney tumors in children, and on this account the author urges the importance of a microscopic examination from several parts of the growth. Necrosis and hemorrhage in the central parts are frequently seen, but no hematuria or metastases are observed, as are so frequent in the renal growths of adult life.

The tissues found in these tumors are smooth and striped muscular fibers, elastic fibers, adipose tissue, myxomatous tissue, fibrous connective tissue, cartilage, and glandular tissue. The author differs from Birch-Hirschfeld who states that these tumors arise from misplaced Wolffian body elements. The presence of many of the elements found in these tumors is thus explained, not so, however, the cartilage or striped muscular fibers. The Wolffian body does contain non-striped muscular fibers and according to Eberth the striped muscular fibers result by a process of metaplasia. Wilms is opposed to this theory and states that, whereas the Wolffian body is in part responsible for the presence of many of the elements, the other tissues probably arise from young undifferentiated embryonal tissue from the mesodermal layers.

A critical survey of the literature on the subject is presented and the author gives a description of the eight cases that he had the opportunity of examining microscopically. Then follows a minute description of each tissue separately. All clinical data are purposely omitted in the work. Several drawings from embryologic sections are included in the work, also a colored plate, describing some of the author's findings.

All in all, this is a book that every pathologist should obtain and study and we look forward with pleasure to the succeeding sections.

AN AMERICAN TEXT-BOOK OF DISEASES OF THE EYE, NOSE, AND THROAT. Edited by G. E. de SCHWEINITZ, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College of Philadelphia; and B. ALEX. RANDALL, M.A., M.D., Ph.D., Clinical Professor of Diseases of the Ear in the University of Pennsylvania. Illustrated. Philadelphia: W. B. Saunders, 1899.

THIS unusually complete and thoroughly prepared work is essentially a text-book, and, as such brings into prominence the practical side of the subjects treated, while, on the other hand a volume is presented to which the practitioner may refer for information upon a series of special subjects. The collaboration method employed in the preparation of the work, which has so often demonstrated its value, shows here one of its greatest advantages, that of presenting the views of experts, in a series of articles written by men who are authorities on the chapters assigned to them, while, as Howell has said, the student gains the point of view of a number of teachers, reaping, in a measure, the same benefit as would be obtained by following courses of instruction under different instructors.

In the portion of the work devoted to the eye, embryology, anatomy and histology are discussed by Piersol, physiological optics by Dennett and Cutter, functional examination by De Schweinitz, ophthalmoscopy by Randall, refraction by Jackson, while seventeen chapters are devoted to diseases and injuries of the orbit, eye, and appendages, and seven to ophthalmic surgery. The appendix contains valuable contributions on the subject of color-blindness, form and color-vision standards, the Roentgen-rays in ophthalmic surgery, the practice of ophthalmic operations on animal's eyes, and Mier's organisms in etiological relationship to ocular diseases.

Where all is so good, the singling out of articles might seem invidious, yet mention should be made of the care bestowed on even the shortest chapters, and of the uniform excellence of the illustrations, especially those representing the fundus oculi, as well as those accompanying the chapters by Holden, Weeks, and Piersol. In the portion of the work devoted to the ear, the anatomy, physiology, diseases and injuries are discussed in thirteen sections by prominent otologists; while the diseases of the nose and throat are described in twenty sections by Asch, Sajous, Jonathan Wright, Roe, Myles, and others equally well known.

This book may be recommended with confidence and commended to students and practitioners of medicine and surgery in general, as well as to those interested as specialists in the subjects of which it treats in particular. It will undoubtedly take equal rank with the other volumes of the "American Text-Book" series, which have been so well received by the profession.

GENERAL PATHOLOGY, or the Science of the Causes, Nature and Course of the Pathological Disturbances Which Occur in the Living Subject. By DR. ERNST ZIEGLER, Professor of Pathological Anatomy and of General Pathology at the University of Freiburg. Translated from the Ninth revised German Edition. Edited by ALBERT H. BUCK, M.D., of New York. New York: William Wood and Company, 1899.

ANY special criticism or extended review of this well-known work on pathology would be somewhat out of place at the present time. That the work is in constant demand is attested by the fact that nine editions in the original language have appeared during a comparatively short period. Many important data on the subject of cause and effect of disease have been noted in recent years, and the incorporation of these facts gives the book a distinct clinical value. The translators and editor have performed a most useful service in giving this work to English readers, but an important feature of the German edition, namely, the extensive bibliography at the end of each chapter, has been omitted, as "its publications would require fully two hundred additional pages."

As it is, the book contains nearly 600 pages of closely printed matter with an abundance of satisfactory illustrations, many being in colors.

The introductory chapter deals with health and disease, and the problems of general pathology and pathological anatomy. Following this are ten chapters devoted to the cause, origin, and course of disease; disturbances in the circulation of the blood and the lymph; retrograde disturbances of nutrition and infiltrations of the tissues; hypertrophy and regeneration of the tissues and organs; inflammation and the associated processes of repair; tumors; disturbances of development and the resulting malformations; fission-fungi which exist as parasites and the diseases caused by them; mold-fungi and yeast-fungi and the diseases caused by them, and the animal parasites.

We do not hesitate to say that this valuable work will become popular with all English-reading students, containing as it does an almost inexhaustible fund of knowledge and being written in a straightforward and concise manner. We earnestly commend the book to those interested in general pathology.

THE HYGIENE OF TRANSMISSIBLE DISEASES: THEIR CAUSATION, MODES OF DISSEMINATION, AND METHODS OF PREVENTION. By A. C. ABBOTT, M.D., Professor of Hygiene and Bacteriology in the University of Pennsylvania. Philadelphia: W. B. Saunders, 1899.

DR. ABBOTT'S book opens with a historical and argumentative introduction to prove, if such proof were necessary, the value of the hygienic and sanitary work of recent years. The exciting and predisposing causes of disease are then set forth, especial attention, of course, being paid to the rôle of parasites and bacteria. This is followed by a carefully written exposition of the causes, modes of dissemination and prevention of special diseases, such as typhoid fever, tuberculosis, the bubonic plague, Asiatic cholera, venereal diseases, rabies, and the other more common acute infectious diseases. Prophylaxis in general against infectious diseases is next considered and the precautions to be observed in the management of communicable diseases and a chapter on quarantine ends the work.

A careful reading of the book shows that the author has taken pains to emphasize throughout the prevention of disease. His article on typhoid fever may be taken as a model of the rest of the book. He shows—as is now universally acknowledged and believed—that polluted food or drink is the one great source of this disease. The series of instructive charts showing the increase of typhoid fever under unfavorable conditions of water-supply and sewage, and its decrease when these faulty elements were improved, offers striking, in fact, incontrovertible evidence of the truth of this position. The study of epidemics, too, is didactic to a high degree as there presented, especially that of the Philadelphia epidemic in 1897–8, which the author had the opportunity of personally observing. The directions for domestic prophylaxis in typhoid fever contain those that are usually followed by the physician of to-day and includes one suggestive hint that is probably not widely known: The removal of stains of blood or fecal matter from the linens used by the patient may be accomplished by soaking them for two or three hours in a *cold* three-per-cent. solution of carbolic acid and finally rinsing them in a fresh portion of the same solution. This will remove all stains, which will not, however, disappear if the linens are first subjected to moist heat by boiling, which process they should later go through.

The directions for prophlyaxis of the other transmissible diseases—and we are glad to note that the author carefully eschews the rapidly disappearing terms "contagious" and "infectious"—are equally exhaustive and full of practical suggestions.

The practitioner will find in the chapter dealing with the precautions in the management of communicable diseases all that modern hygiene can offer in the way of prevention; and this is much more than is ordinarily surmised. The chapter on quarantine is a short *résumé* of this important function.

The author has freely given credit to writers on hygienic and sanitary subjects, and has produced a book which is important for more reasons than that it is the first of its kind. It is scientific, but not too technical; it is as complete as our present-day knowledge of hygiene and sanitation allows, and it is in harmony with the efforts of the profession which are tending more and more to methods of prophylaxis. It contains so much that is worthy of being read that we wish the laity, too, could receive the benefits of its teachings. For the student and for the practitioner, it is well-nigh indispensable. The illustrations, some of them in colors, are mainly of charts, bacteria and parasites, and disinfecting apparatus.

THERAPEUTIC HINTS.

For Loss of Eyelashes.—When the eyelids do not show redness or other sign of inflammation, attention should be given to the general health, possible rheumatic conditions treated, and local inunctions be prescribed as follows:

℞ Ac. gallici . . . . . gr. viii
Ol. ricini . . . . . ʒ ss
Ol. lavandulæ . . . . . gtt. iv
Vaselini . . . . . ʒ v.
M. Ft. unguentum. Sig. External use.—*Trousseau.*

To Remove Freckles.—

℞ Hydrargyri chloridi corros. . . gr. viii
Zinci sulphat. } aa. . . gr. xv
Plumbi sulphat }
Aq. dest. . . . . ʒ viii.
M. Sig. External use.

Rub the skin with this lotion for half a minute night and morning, allowing it dry in the air. If this prove too irritating, use the lotion only at night, and in the morning apply the following ointment:

℞ Zinci oxidi . . . . . gr. lxxv
Vaselini . . . . . ʒ i.
M. Ft. unguentum. Sig. External use.

ORIGINAL ARTICLES.

CHRONIC STIFFNESS OF THE VERTEBRAL COLUMN.

BY CHARLES L. DANA, M.D.,
OF NEW YORK.

Historical.—A stiff ankylosed spine, without involvement of other joints, or with involvement of only the hip and shoulder, is rather rare, except as the result of trauma, or Pott's disease. It is seen, however, following chronic or gonorrheal rheumatism, in arthritis deformans, spondylitis deformans, as an occupation kyphosis of certain laboring classes (the *duplicature champêtre* of French writers), and in paralysis agitans. Recently two new types of this condition have been described and much discussed in French and German literature, and I wish to report some examples.

Chronic spondylitis was described many years ago, the malady being classed with arthritis deformans. I recollect learning as a student that arthritis deformans had two types, one central or senile. and the other peripheral. In the central type the disease affected the joints of the hip, vertebræ, and shoulder, and proceeded peripherally. This I learned as a hospital interne, and it was the doctrine taught by Senator in "Ziemmsen's Cyclopedia, Vol. XVI., 1877." Chronic ankylosing spondylitis had, however, been described at least as long ago as 1864, by Blezinger and Von Thaden, and a case was cited by Brodhurst in "Reynold's System of Medicine" in 1866; also by Leyden in his work on "Diseases of the Spinal Cord." Dr. Bradford of Boston also reported two cases in 1883, in the *Annals of Anatomy and Surgery*, Vol. VII., p. 279. One of these cases was that of a man thirty-six years old, previously perfectly healthy, without any family or personal history of rheumatism. During that year he had an attack of urethritis, followed by rheumatism, which involved a number of joints, and also the back. The inflammation in the joints subsided, leaving him with a stiff spine. He subsequently had a number of other attacks of gonorrheal rheumatism, each ending with an increased rigidity of the spine, until finally it became absolutely immobile, and he was left in that condition, but otherwise perfectly well.

The second case of Dr. Bradford's was that of a woman of thirty-one, who had an attack of subacute rheumatism, ending gradually in spondylitis, with ankylosis of the spine. All of the joints became normal, except those of the vertebræ. These cases are probably not so very rare. They point to the fact that rheumatism may lead to a permanent ankylosis of the vertebræ.

Dr. W. Gilman Thompson refers to the central type of arthritis deformans, in his article on this disease, in the "Loomis–Thompson System." Gowers makes some reference to it in his "Text-book," Vol. I., p. 257, and Beneke[1] describes the pathological anatomy of spondylitis deformans.

The foregoing sketch, though not complete, will give some idea of the attention paid, up to within a few years, to this subject.

In 1892 Professor von Bechterew reported five cases of "Stiffness of the Vertebral Column with Kyphosis as a Special Disease Type."[2] The patients were women, and the ages were fifty-six, fifty-two and thirty-nine, the ages of the other two not being mentioned. They suffered from a chronic progressive ankylosis of the vertebræ, with marked arching forward of the spine. This was accompanied with intercostal pains and paresthesiæ, atrophy, and paresis of the trunk muscles, but without any involvement of the joints of the limbs. There was a history of heredity and trauma in three of them.

In 1894 Oppenheim published in his text-book, a short description of a form of arthritis deformans in which the vertebræ were affected, leading to ankylosis and giving much the same symptoms that Bechterew described. In 1897 Bechterew[3] reported another case in a man of fifty-two, and gave to his malady the following symptom-complex: first, immobility of the vertebræ, in whole or in part, without any great pain on percussion or movement; second, marked arching forward of the spinal column, especially of its upper part, as the result of which the head is pitched forward and appears sunken into the neck; third, a paretic condition of the muscles of the trunk, neck, and extremities, with slight atrophy of the shoulder muscles; fourth, lessened sensibility, chiefly in the distribution of the cutaneous nerves of the neck and dorsal region, and less in that of the lumbar region; fifth, various irritative phenomena of the nerves of the neck and trunk, such as neuralgia,

[3] *Deut. Zeitsch. für Nervenheilk*, vol. ii, p. 327.

paresthesia, and twitching of limbs. The breathing was abdominal, and the chest flattened. The shoulders and hips were not usually affected.

In 1898, P. Marie and Astie reported a case of what they termed hereditary traumatic kyphosis, in an elderly man. The symptoms resembled very much those of Bechterew's cases. A hereditary history was present. An illustration of this case is given in Fig. 1. In 1899, Bechterew reported

FIG. 1.

"Hereditary traumatic" type of kyphosis (case of Marie and Astie).

three other cases.[1] In two of these the hip and knee-joints were involved. He also publishes here the report of an autopsy upon one of his earlier cases, characterized by kyphosis, vertebral ankylosis, thoracic pains, and atrophy of the trunk muscles. This autopsy showed some atrophy and ankylosis of the vertebræ, but no inflammatory disease. There was no pachymeningitis, but there was a degenerative inflammatory process in the thoracic pia mater involving especially the posterior roots and ganglia, and to some extent the anterior roots. There were some secondary changes in the cord. Bechterew infers that the kyphosis was primarily the result of the root meningitis, with resulting atrophy of the trunk muscles and an ankylosis and kyphosis from paralysis of these. (See Fig. 2.) Similar observations to those of Bechterew have been made by V. Kohler,[2] Beer,[3] Schatalow,[4] S Popon,[5] and Baumler.[6]

Several cases of this kind have come under my observation. I report two which are most typical:

CASE I.—Mr. E. H., aged forty-four, United States, married; occupation, a manufacturer. The patient lives in an interior town of this State. His father died at the age of eighty, of old age; his mother died at sixty, of some cardiac trouble. There is no ancestral history of rheumatism. The patient is the youngest of six children, all of whom are now dead, and two of whom had epilepsy. The patient was a man of good habits, temperate in the use of alcohol, and did not use tobacco. He never had any specific trouble. He was the father of six healthy children. He had been a hard working man, but had had no serious illness before the present time. At the age of twenty he had inflamma-

FIG. 2.

Bechterew's case of chronic stiffness of the vertebral column, showing cross-section of dorsal cord with thickening of *pia mater* and sclerosis of cord; also changes in anterior roots, posterior roots and in posterior spinal ganglia.
(From *Deut. Zeitsch. f. Nervenh.*)

tion of the left hip, and some other joints, probably rheumatic in character. He recovered from this but suffered more or less from rheumatism for two or three years. He then continued free from it for a space of about twenty years.

His present trouble began about three years before I saw him, which was in June, 1896. At that time he had a rash of some kind, which he could not describe very well, and as the result of it, he was

sick for about three months. Then he noticed a gradual stiffness developing in the upper part of his spine, and at the same time the shoulders became stooping, and the back more and more arched. This condition was associated with some pain and sense of discomfort in the back, and a feeling at times of constriction around the chest. There was, however, no attack of sharp pain and no acute illness, which laid him up. The process gradually advanced until the whole vertebral column was perfectly rigid and very much arched, so that he walked with his body inclined at a great angle. The head also became somewhat immobile, so that he could not move it upward or forward much, and the lateral movements also became lessened. There was very little trouble with the hip joints, and he could walk fairly well. The arms were strong, but the movements of the shoulders became rather limited.

Examination.—When I saw the patient, in 1896, he was a man of medium height and thin body, very much stooped over. He was not, however, badly nourished or very anemic. He could arise from the sitting position only with a good deal of difficulty. When lying flat on his back, he could not get up without help. When standing he was able to walk with ease. The forearms were strong and the grip of the hands good. There were no deformities of the joints, of the hands, or of the elbows. The shoulder-joints were somewhat stiffened, and he could get his arm back of his head only with difficulty. The head was drawn down and forward, and the anteroposterior movements were very limited. Lateral movements were almost abolished. The muscles of the neck were atrophied to some extent. The back presented an extraordinary arch, produced by flexion of the dorsal vertebræ. The movements of the chest were very limited, the measurement from the mammary line being twenty-nine inches, and the utmost expansion being a half inch. The hip-joints were a little stiff, but the joints of the knees and the feet were normal. There were no exostoses observable upon the vertebral column.

Along the dorsal spines there was some tenderness on percussion at the fifth, sixth, and seventh dorsal, with a sense of constriction, but no pain on trying to breathe deeply. He had some neuralgic pains in the chest, especially at night. Occasionally he would have twitchings in the legs, and the knee-jerks were somewhat exaggerated. He had difficulty in sleeping well at night because he would get stiff and numb about the shoulders and chest from lying in one position, being unable to move himself. Anesthesia, ataxia, and disturbance of the bladder or rectal functions were absent. He had a cardiac systolic murmur, and the heart was a trifle hypertrophied. The kidneys and urine were normal. The patient's visceral functions were, in general, in very good condition.

I saw the patient again four months later. At that time he had improved somewhat in strength. He could walk further, and had fewer cramps in the legs. He was seen again by me a year later. At that time there was more kyphosis. The chest measurements were the same. The arms were a little weaker and less useful. The stiffness in the hip-joints had increased a little; otherwise his condition was not much changed. Through a letter recently received from his physician, Dr. Higgins, I learn that he is not much changed. He is still able to ride a bicycle.

CASE II.—Francis H., aged fifty-two years, married, German by birth; occupation, cigar-maker. The family history told of no hereditary taint of any kind, the parents being long-lived and free from rheumatic or nervous maladies. The patient himself had lived a regular, temperate life. He had been a rather hard smoker, but had drank little, and was regular in his habits. The man never had any venereal disease. His wife had had one child and no miscarriages. There was no history of injuries.

The patient himself had always been well except for occasional pains in the back. His present trouble began about a year before I saw him. At that time he began to complain of pain and stiffness in the back. These pains were continuous and squeezing in character, and they ran sometimes down into the arms, especially into the left, but never involved the legs nor the viscera. The pains did not resemble those of angina pectoris, as they were not accompanied by any sense of suffocation. These pains and the stiffness in the back continued gradually without much intermission. The patient, at the end of six or seven months, went to Europe, and was seen by Professor Erb, who made a diagnosis of locomotor ataxia and sent him to Nauheim, where he received the baths without benefit. He came to me in the winter of 1891, when I made my first examination The patient was a man of average physique, somewhat thin, and weighing about 140 pounds. He looked yellow and anemic. His gait was slow and rather feeble, and he carried his back in a perfectly rigid fashion.

Examination showed that the vertebral column was entirely rigid in the cervical and dorsal regions, there being some movement in the lumbar region. The shoulder-joints also were somewhat stiff. The patient could use his forearms and hands, but could only raise the hands to the shoulders very slowly and with difficulty. The head could be moved forward; laterally, only to a limited extent. The spinal column was very slightly arched forward. There was no distinct kyphosis. The movements of the chest were nearly abolished. There was however a very slight power of expansion. There was no stiffness or ankylosis of the joints of the lower extremities and no rheumatic deformities of any of the joints. The patient complained of an almost continuous feeling of constriction, sometimes amounting to pain, in the region of the fourth and fifth dorsal vertebræ, where there was a little tenderness on percussion, but absolutely no kyphosis. The patient could be hurt somewhat by movements of the trunk, lateral and antero posterior, but he did not mind it much. Jumping, coming down on the heels, and pressure on the top of the head, did not caused pain. There was, at one

time, loss of knee-jerks, but these subsequently appeared. Anesthesia, ataxia, paralyses, and involvement of the bladder and rectum were absent. The patient's general bodily functions were normal, except that he had little appetite and slept badly, on account of the discomfort in the chest.

The case, of course, suggested one of spinal tumor or of vertebral caries, but the subsequent history enabled me to exclude these conditions. He went at one time to Dr. Sayre, who could not find evidence of caries. There was no evidence either of an aneurism, which would not, in fact, have explained the ankyloses of the cervical vertebræ or of the shoulder and neck. The patient under counter irritation, baths and tonics, improved considerably for the next three years while he was under my care, and during those three years of observation, his symptoms changed very little. The rigidity of the back continued, no kyphosis or deformity developed, and in spite of the discomfort, he was able to go out a little, to play cards, and take some of the enjoyments of life. He, even at this last period, showed no signs of involvement of the joints of the extremities.

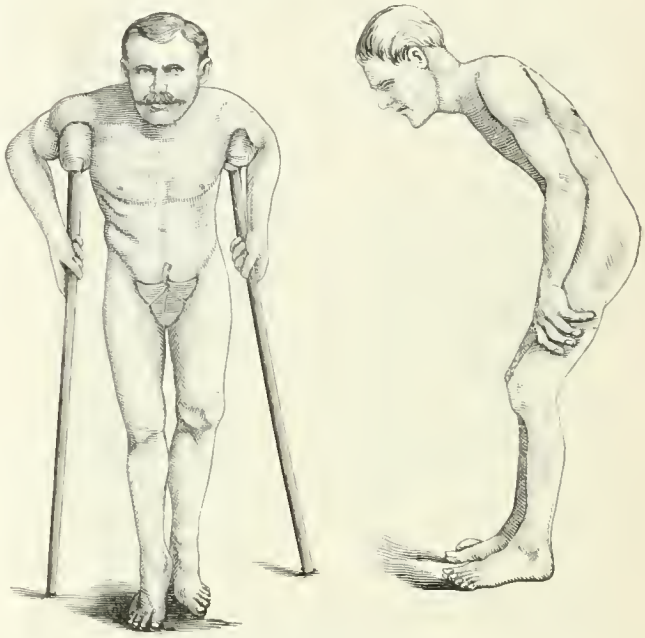
A recent examination shows little change, though his malady has lasted nine years, quite long enough to exclude tumor or tuberculosis.

FIG. 3.

Strümpell; case of chronic stiffness of the spinal column.

While Bechterew was studying this type of spinal trouble, observations upon another type were being made. In 1884 Strümpell, in his "Textbook of Medicine," under the head of Arthritis Deformans, says: "A remarkable, and as it seems to us, unique disorder may be mentioned in passing. It leads very gradually and painlessly to a complete ankylosis of the entire spinal column and the hip-joints, so that the head, trunk, and thighs are firmly united and completely stiffened, while all the other joints retain their normal mobility." Strümpell had seen two cases. In 1897 he reports a third case in detail, and[1] gives an illustration which is here reproduced (Fig. 4). The patient was a peasant, aged thirty-nine, with no rheumatic, hereditary, or traumatic history, whose trouble began with pain and stiffness in one hip.

FIG. 4.



Marie's first case of spondylosis rhizomelia. Front and lateral views.

The hips and spine in three and a half years became firmly ankylosed. He had few of the trunk pains described in the other class of cases.

Within the last year a large number of articles have been written upon this form of ankylosing spondylitis which, it is claimed, is different in character and type from forms previously described. Special attention has been drawn to it by the article of Dr. Pierre Marie.[2] He there describes three cases of chronic ankylosing spondylitis which involve the vertebræ, the hip and shoulder-joints; that is to say, the spine- and root-joints. He calls the affection spondylosis rhizomelia (*spondylos*, spine; *rhizo*, root; *melos*, extremity).

Marie's first case (Fig. 4.), he says, was seen by him in consultation with Charcot, in 1890. Neither of them was at that time able to make a definite diagnosis, but thought that it was a form, perhaps, of Paget's disease. Later, Marie having seen two other cases, and having noticed the suggestions of

[1] *Deutsche Zeitsch. für Nerv.*, vol. ii, p. 338.
[2] Marie, "Spondylosis rhizomelique," *Revue de Medecin*, April, 1898.

Strümpell, ventured to publish his observations in detail. The condition that he described is one characterized by a progressive ankylosis involving usually, first the hip-joints, then the vertebral column and the shoulder-joints. Sometimes one or both of the knees is affected, but never any of the smaller joints. It is not associated with any form of rheumatism or gout. The process is a chronic one,

FIG. 5.

Marie's second case of spondylosis rhizomelia. Front and lateral views.

and accompanied with a little pain. Some exostoses are observable upon the sacral bones and the bodies of the central vertebræ, and also a flattening of the thorax and pelvis, with loss of thoracic respiration and muscular atrophy in the dorsal and gluteal regions. The smaller joints are not affected. The malady attacks men only, and occurs at middle life and somewhat later. I reproduce here illustrations of some of Marie's cases. (Fig. 4 and 5.)

Since Marie's description there have appeared articles by Mutterer,[1] Hoffmann,[2] Professor Valentini[3] of Dantzig, L. E. Bregmann[4] of Warsaw, and Zenner of Cincinnati.[5]

I have here the report of a case of this affection which is now under my observation at the Montefiori Home.

CASE III.—Benni B., aged thirty-six years; occupation, tailor; nativity, Russian. Father died at sixty-five years; mother at sixty years. No rheumatic, tubercular, or neuropathic history in the family. Two children living; no miscarriages. The patient's personal history entirely negative, moderate in habits, no specific disease, moderate drinker. no smoker. No previous history of rheumatism, No accidents or emotional disturbances.

His present illness began five years ago at the age of thirty-one from no assignable cause. He first noticed pain in the left knee, which continued for some time, and then extended to the hip, where it continued. This pain and stiffness in the hip and knee progressed until he was obliged to give up work, and was admitted to the Presbyterian Hospital in 1894. He left there improved and had no symptoms for a year, during which time he worked. The pain then returned in the left hip and he was admitted to the Montefiore Home in 1895, with a diagnosis of tubercular coxitis, having had some history of cough and night-sweats. On admission, a careful physical examination showed no evidence of tuberculosis in the lungs. He was anesthetized, and some of the adhesions of the hip were broken up. He was seen at this time by Dr. Gibney, who considered it a case of tubercular coxitis, and he was placed in an apparatus for two months without any improvement. His trouble rapidly extended to the

FIG. 6.

Author's case of so-called "spondylosis rhizomelia."

back and to the right hip and right knee, until, at the present time, he has complete rigidity of the entire spine and of both hip-joints, as well as a great rigidity of both knee-joints. None of the other joints are affected, however, and the patient's elbows, wrists, ankles, and small joints of the hands and feet are quite normal. He has no Heberden nodules upon the hand.

The *status praesens* is as follows: I quote here

[1] *Deut. Zeitsch. für Nervenh.*, bd. xiv, hft. 1 and 2, p. 145.
[2] *Deut. Zeitsch. für Nervenh.*, bd. xv, hft. 1 and 2, p. 28.
[3] *Deut. Zeitsch. für Nervenh.*, bd. xv, heft 3 and 4, p. 239.
[4] *Deutsch. Zeitsch. für Nervenh.*, 1899, bd. xv, heft 3 and 4, p. 254.
[5] *Journal of Nervous and Mental Diseases*, vol. xxvi, October, 1899.

from a careful report made by Dr. Joseph Fraenkel, to whom I am greatly indebted for calling my attention to the case, and for close observation on it.

Pulse, 78; soft. Respiration, 18. Temperature normal. The man lies in a chair, rigid as a poker, and can stand only with difficulty; as he stands his head is held rigidly forward; the rigidity extends throughout the entire spinal column, from the fourth cervical downward; he can move his head backward and forward and somewhat laterally, though movements are limited in all directions (except the nodding of the head). The left thigh is adducted, rotated inward and slightly flexed. The right thigh is similarly involved, though to a less extent. The left foot is everted, with marked fixation at the ankle-joint. The leg is slightly flexed, especially the left sacrum, due to counter-irritation, with a few scars over the body.

The patient has a low forehead, a symmetrical head, flaring ear, *arcus senilis*, fibrillary contractions of the tongue. The pupils are equal, react well, with some nystagmus on lateral movements of the eyeball, especially to the right; facial innervation normal; pharyngeal reflex present; dry atrophic pharyngitis; dry rhinitis.

Upper extremities. The motor power is diminished, especially of the right side, and the left arm is greater in volume than the right. There is no ataxia. Muscles of right arm especially somewhat flabby. Reflexes elicitable. Mechanical irritability increased. Abdominal reflexes active; left cremasteric reflex active. Large scar in right groin. Right knee-jerk is very active, the left is elicitable, Achilles jerk not elicitable, plantar reflex active.

Fig. 7.

Same case.

the left one. The knees are both rigid, with fusiform swelling, the left being greater than the right, but no redness, no tenderness, no heat; some pain on attempting to flex the left leg is felt in the knee. Contractures of semimembranosus and semitendinosus muscles are marked, but less than of the other hamstring muscles. There is contracture and rigidity, but not marked, of the gastrocnemii groups, with rigidity of the tendo-Achilles of the left foot. There is some creaking in the right shoulder, though no limitation of motion. The toes are not involved in either foot. There is total rigidity of the left hip, and almost the same in the right. There is marked atrophy of all the muscles of both thighs, especially the left; prominence in both trochanters; prominence and apparent enlargement of the entire sacroiliac region; atrophy of glutei groups; tension of the abdominal group of muscles, and scar atrophy over

Mechanical irritability is diminished and uniform for both sides.

There is marked rigidity and stiffness of the entire thorax and the intercostal spaces are rigid. Lungs normal. Heart sounds rather week, with some aortic accentuation at second interspace. Liver and spleen normal. Urine normal as to albumin, sugar, and casts! No sensory disturbances.

From this view of the history of the subject it appears that there are two different types of chronic stiffness of the vertebral column for which individual characteristics are claimed. The first is that referred to by Strümpell, and described by Marie, as *spondylosis rhizomelia*, and of which a number of cases have been reported by others. In this the malady begins usually in the hip joints, and pro-

gresses steadily upward, affecting the spine and the shoulder joints. This is accompanied with a very marked rigidity of the spine, and some kyphosis, but this is not always very great. The patient does not suffer a great deal of pain, and does not have intercostal neuralgias or paresthesias or shooting pains in the nerves of the leg and arm.

The second type is that described by Bechterew, of which some examples have been reported. Here the trouble begins in the spine primarily, and is accompanied with a progressive stiffness and arching of the back, which may become very great. The patient suffers a great deal from intercostal pains, while the joints of the hip and shoulder are not very much, if at all, involved. There is, according to Marie, a hereditary history, and often a history of trauma, and Marie calls it the "hereditary traumatic type."

Pathology of the Affection.—The essential point in the pathology of the spondylosis rhizomelia, or Strümpell—Marie type, is, of course, to know whether it is not simply a form of arthritis deformans. The fact that Charcot saw Marie's first case, and, despite his enormous experience with rheumatoid arthritis, did not consider it such, must lead one to, at least, hesitate in asserting that there is no essential difference. The essential points which it is claimed, differentiate spondylosis, are: first, the fact that it produces directly an ankylosis, without any previous inflammatory swelling, with exudation and proliferation; also, that it produces this ankylosis directly, and not as the result of a deformity with secondary ankylosis, as in the case of arthritis deformans; second; that it begins in the vertebral joints, and extends thence to the hips and other large joints; third, that the smaller joints are never affected, or only rarely, in one or two cases; fourth, the internal organs and nervous system remain normal; fifth, the clinical picture is one of great uniformity; sixth, there is no previous history of rheumatism or gout, and no evidence of arthritis deformans in other parts of the skeleton; seventh, the affection occurs usually in men in about middle life.

As for the other or Bechterew type it seems to be a secondary affection, and may be caused by a chronic meningitis, or may in some cases be a form of rheumatoid arthritis.

Such is the status of the question at the present time. I must confess that, so far as my personal observations and reading go, it does not appear to me that the case for any specifically new malady is made out, and I am inclined to believe that spondylosis rhizomelia is after all a form of arthritis deformans essentially allied to that trouble in etiology, symptomatology, and progress, while Bechterew's cases suggest that disease in some cases, in others syphilitic meningitis.

50 W. FORTY-SIXTH STREET.

VACCINATING A NATION.

BY GEORGE G. GROFF, M.D.,
OF SAN JUAN, PUERTO RICO;
LATE MAJOR-SURGEON U.S.V., DIRECTOR OF VACCINATION IN PUERTO RICO.

IT is generally known that smallpox is endemic in all Spanish-American countries. Puerto Rico was no exception to this rule when occupied one year ago by the American troops. Indeed, the remark has been jestingly made that the people seem to think little more of smallpox than of an attack of prickly heat.

In December, 1898, it became known that the disease was prevailing in many portions of the island and that an epidemic was threatened. In January, 1899, the reports of the Post Surgeons were examined for November and December, and it was discussed that they had called attention to some 3000 cases of this disease, occurring during these two months, in sixteen of the seventy-one municipalities into which Puerto is divided. In view of these facts, the Governor-General on January 27, 1889, issued General Order No. 7, of which the following is the first paragraph:

I. "The inhabitants of this Island must be protected from smallpox. Every resident who has not had this disease will be vaccinated, and hereafter all infants must be vaccinated before reaching the age of six months."

This order appointed five directors of vaccination, five inspectors of vaccination, named all post surgeons as inspectors, and required them to render all the assistance possible in the undertaking. The whole work was under the direction of the Chief Surgeon of the Division, Major John Van R. Hoff. The experience of six months having demonstrated that all virus from the United States had lost its virility on reaching the island, it was decided to establish a "vaccine farm" at Coamo Baths, where cattle were abundant and facilities for the work already existed. This was done and the establishment placed first in the command of Major Azel Ames, U.S.V., later in charge of Captain F. P. Reynolds. U. S. A. A native cattle dealer secured the animals for use at a cost of an average of one dollar per head.

It is proper here to remark that bovine virus had long been used in Puerto Rico. The native machinery for its distribution was as follows: There was a Central Institute of Vaccination at San Juan, where little more was done than to keep the virus

alive. In each municipality there was a public vaccinator. When it was decided to vaccinate a village or barrio, the vaccinator of the municipality would secure some "pure" virus from the Director of Vaccination at San Juan, with this he would inoculate one or more calves, drive them to the village to be vaccinated, and on the appointed day all the people would assemble and the operations would be performed with virus taken directly from the animal. So performed, it is said, nearly all the operations were successful.

In the beginning of the work, the animals were tested for tuberculosis, but this disease being found absent, this test was in a short time discontinued. The men engaged in the work were divided into three gangs, each in charge of an acting assistant surgeon of the army. First, those testing for tuberculosis; second, the vaccinating squad; third, those collecting the virus. The work was done under wall tents, while the cattle were unconfined and lived in the open fields. No trouble was experienced in producing about 15,000 points each day. Each animal furnished on the average 500 points, the maximum being 3700 points. Since the animals were unconfined, they rubbed themselves removing the scabs, and there was doubtless some loss of virus. After being coated with virus the points were dried, the product from each animal placed in a separate tin box, sealed and sent to the packing station. There they were counted into bundles of 100, wrapped in oil silk, and with wrapping paper and securely tied. Over all a label was pasted giving the number of the animal and the date when the virus was taken. These packets of 100 points were again enveloped in cotton and from 2000 to 4000 points made into packages and daily mailed to the different directors.

The first plan was to vaccinate the people, using hospital corps men who were to be trained for the work as operators. Each director, under this plan, was to have an acting hospital steward, and ten enlisted men. Later it was thought best to employ native physicians, and their assistants, here called *practicantes*. Ten of these were allowed to each director, and were paid. Physicians received $50 in gold, practicantes $25 in gold and scribes 30 pesos per month. Physicians were able to give some attention to their practices meanwhile.

Preliminary letters were addressed to all the physicians on the island, also to all the alcaldes (mayors) asking their cooperation. The island of Puerto Rico is divided into departments. Each department into municipalities. There are seven departments and seventy-one municipalities in the island. Each municipality is subdivided into barrios, which nearly correspond to townships in the States. Each municipality is presided over by an alcalde, who is mayor, school commissioner, county commissioner, and sheriff, all in one. Each barrio is presided over by a commissario de barrio. The alcalde communicates his orders to the commissarios, and they to the people. Fortunately, the people are accustomed to obey their alcalde, and when he issues a proclamation for them to appear at a certain house on an appointed day to be vaccinated, most of them obey. Some, however, have excuses, as of old.

Carefully prepared instructions were issued to vaccinators, and the inspectors endeavored to keep them up to these rules.

Instructions for Vaccinators.—1. The hours of vaccination will be from 8 A.M. to 11 A.M., and from 2 P.M. to 5 P.M.

2. Vaccinators will be dressed in clean, white clothing at all times while at work. Before beginning work, and frequently during the process of the same, they will disinfect their hands with soap and water, using a nail brush, and follow this by immersing the hands in bichlorid solution, 1 to 1000. Vaccinators are responsible for the cleanliness of the instruments and materials used by them, and for the efficiency of their work.

3. Before an operation, the skin of the arm will be washed thoroughly with soap and water, then washed with bichlorid solution, 1 to 1000, and dried with a clean towel.

4. Vaccinations will be done on the left arm at about the middle of the external surface, and in two places half an inch apart. The skin is to be scarified in each place over an area of about 1 cm. or ⅓ inch, until a little serum exudes. Scarification may be done with a cambric needle, or with a lancet. After scarifying, the vaccine point will be dipped in sterile water and then *thoroughly* rubbed over the scarified surface. The arm should remain uncovered until it dries, and no person should leave the room until the arm is dry.

5. If needles are used for scarifying, they should first be boiled for half an hour and then kept in carbolic solution, 1 to 40, until needed. A needle should be used for but one vaccination in a day. At the end of each day the needles used are to be collected and disinfected, as above indicated, for use on the following day. If a lancet is used immediately before each operation it shall be dipped into carbolic solution, 1 to 20, and then passed through the flame of an alcohol lamp.

6. Each vaccinated person should be instructed that he is not to scratch the sore, nor to injure the vesicle nor to remove the scab, but to let it drop off. He should be directed to keep the body clean, and if the arm becomes painful he may cover the sore with a cloth wrung out in very hot water.

7. All persons presenting themselves for vaccination who appear to be suffering from any febrile or exhausting or skin disease which would cause complications, should

not be vaccinated until their cases have ben passed upon by the inspector.

8. All persons should be vaccinated as nearly as possible, in the order in which they present themselves.

9. All used vaccine points must be preserved and returned to the Vaccine Depot at Coamo.

Schedules for the itineraries were made out for the physicians in each municipality, which he was expected to follow, going over the ground twice, once to vaccinate, and a second time to grant certificates, and revaccinate all in whom the first operation failed. They were printed as hand-bills, and widely scattered over every district.

Each director had his office in a central town, where he could receive and distribute the virus readily. It was received from the "farm" and dispatched daily, and could sometimes be used the second day after taking. On the appointed day the director dispatched the virus to his vaccinators and they began work. At the close of each day's work the scribe with each party reported to the directors, as follows:

Number of persons at work.
Number of persons vaccinated.
Number of certificates granted.
Quantity of virus on hand.
Amount needed on the morrow.
Amount received during day.
Material needed on the morrow.

These reports were forwarded to the director daily from every vaccinator and thus enabled him to have complete control of his work.

The inspectors in their rounds made the following inquiries:

Number of vaccinators at work. Average number of persons vaccinated each day per operator. Are vaccinators clean in dress, person, and hands? How are the arms prepared for operation? What instruments are used in scarifying? Are instruments disinfected after each operation? Is the work thoroughly done? In what condition do you find record books? Is the virus regularly received? What per cent. of operations are successful? Have any bad results followed operation? What difficulties have been met? What suggestions do you make to improve the work?

Each director reported to the chief surgeon weekly, telling of the progress of the work, of the difficulties met with, and the number of persons vaccinated and revaccinated. As each person was vaccinated, his name, sex, age, color, residence, age of virus used, etc, were all carefully recorded. When he returned for his certificate, the result of the vaccination was noted and recorded. In this way a complete record of the work was preserved.

It being feared that the people would not promptly avail themselves of this particular blessing of American citizenship, the circular here presented was issued by the commanding general:

The alcaldes of the several jurisdictions of the vaccination divisions of this department are required to use all their authority to secure prompt compliance on the part of the people with the order of these headquarters requiring all the inhabitants to present themselves for vaccination when notified. Any persons failing to so present themselves either for vaccination, or examination afterwards, as directed, will be punished.

No person who cannot present a duly attested official certificate of vaccination after the date when the official vaccination in his or her barrio or district, is completed, shall be admitted to any school, public or private; shall travel by any public conveyance, visit any theatre or any place of public resort, engage in any occupation related to the public, or receive employment.

All school teachers, managers, employers and others effected by this order, will govern themselves accordingly under penalty.

This circular was issued over the signature of Major-General Henry, Governor-General of the Island.

On June 25th the chief surgeon received a telegram from the "farm" that on that day at 3 P.M., the one-millionth point had been taken. The reports on June 30th, when the work closed showed that in all some 790,000 persons had been vaccinated. Vaccine was furnished free of cost to all physicians on the island, and doubtless 10,000 were vaccinated by them. In all, not much less than 200,000 persons must be immune, having at some time had the disease. Hence it may be considered that Puerto Rico is now protected against smallpox so far as successful vaccination can do it.

Suggestions, based on the experience gained in the work in Puerto Rico, may be offered as of use in similar operations in the future.

1. The work should only be undertaken in the dry season. (2) The virus should be used as soon as possible after its production. (3) Two or three days' supply of virus should constantly be on hand at each station because of accidents from storms and other unavoidable causes, for whenever the people have assembled, there should be virus present with which to vaccinate them without fail. (4) The alcaldes can, if they will, bring the people out to the appointed places. At times they will not exert themselves to do this. On the first failure they should be reported to the military governor, after which there will be no more trouble with this particular official. (5) A single vaccinator can thoroughly cleanse each arm, and vaccinate 200 persons in a day of eight hours. If hurried he can vaccinate 300. If the arms are cleansed and dried

for him, or if this is altogether neglected, he can vaccinate readily 500 persons in eight hours. (6) Physicians, for the small pay offered will not take an interest in this work. The practicantes, for $25 per month, will do honest and faithful work. The economy in employing them is evident.

Many difficulties were encountered. The country and the people were foreign. Their language and customs were strange. Rains swelled the mountain streams to torrents which were often impassible for days at a time. There were no hotels in the country villages, and no means for caring for man or beast, and yet, in three working months, 800,000 persons were vaccinated!

Many excuses were offered for failure to accomplish the work expected. One young physician, just from the University of Madrid, when asked why he did not vaccinate all the people gathered at a cock-fight where he was working, replied, "I feared a thrashing." Another physician said the people had no clothes to wear away from home and that he had to visit each household. This finally became a prevalent excuse and, sad to say, it was often true. Another physician reported that he had to send many people home to take baths, and thus lost time. One physician was discovered dipping each virus coated point into boiling water before using it, declaring he thought better results would follow sterilization of the virus before using it! Not a single death which could be strictly attributed to the vaccination occurred. There were some infected arms, and some of the people and a number of the municipalities asked for relief, because the poor were not able to perform their accustomed labors, but this trouble was not serious. Not a single riot or lesser disturbance occurred. The people generally welcomed the operators.

The total cost of the work was $32,000, or about 4 cents for each person vaccinated, certainly not an extravagant sum for ridding a country of a loathsome disease. At this date, October 20th, not a single case of smallpox is known to either the military or the civil authorities, and it may be considered *stamped out* of Puerto Rico. This is the first time this feat has ever been accomplished in a Spanish-American country. Can a similar result not be attained in the other tropical colonies of the Union?

SAN JUAN, P. R., October 20, 1899.

Measles in Buffalo.—During the three days ending November 13th there were 68 cases of measles reported in the city of Buffalo, and 237 cases have been reported since October 1st. The disease is spreading through many of the public schools. It would seem that they need medical-school inspection in Buffalo.

A BRIEF SUMMARY OF THE INDICATIONS FOR OPERATIONS ON THE STOMACH.[1]

BY MAX EINHORN, M.D.,
OF NEW YORK.

THE greater number of real cures nowadays among patients with digestive ailments are due, firstly, to a more thorough knowledge of their nature; secondly, to the use of more appropriate treatment (dietetic, medicinal, and physical measures), and, thirdly, to operative intervention. Operations on the stomach, although rare in olden times, have been performed during the last twenty or thirty years with increasing frequency. These operations serve to remove disorders which cannot be treated successfully by ordinary measures. They are, therefore, not antagonistic to the medical plan of treatment, but, on the contrary, are in harmony with it and supplementary to it. Among the many authors who have advanced the surgery of the stomach in America, I may be permitted to mention the following: Robert F. Weir, N. Senn, W. T. Bull, Joseph D. Bryant, Robert F. Abbe, F. Lange, Charles McBurney, Willy Meyer, A. McCosh, A. Gerster, F. Kammerer, Roswell Park, Murphy, and last, but not least, W. W. Keen.

While these operations, so distinctly beneficial in suitable cases, are sometimes not given due consideration, they are occasionally performed in conditions for which they are not required. For this reason it appeared to me timely to broach the subject of the indications for operations on the stomach.

The operative procedures upon the stomach are the following: Gastrotomy, gastrostomy, measures to facilitate the outflow of chyme from the stomach (pyloroplasty, divulsion of the pylorus, gastro-enterostomy), resection of part of the stomach or of the entire organ, gastrolysis, gastroplication, gastropexy. It will be best to briefly review each operation separately, and state for what conditions it should be undertaken.

Gastrotomy, simple incision followed by immediate closure of the stomach, is done firstly and principally for the purpose of removing foreign bodies from the gastric cavity. These may have been swallowed or been formed in the stomach. The operation is indicated: (1) If the swallowed body is not smooth, but irregular with sharp edges which may injure the tissues. (2) If it is too large to pass through the pylorus and at the same time gives rise to disturbances; pains, nausea, vomiting, etc. (3) In rare instances, in order to examine the interior of the stomach with reference to the presence of

[1] Read at the Sixteenth Annual Meeting of the New York State Medical Association, held at New York, October 24, 25, and 26, 1899.

malignant superficial neoplasms, ulcers, or ruptured blood-vessels in the case of profuse hemorrhage.

Gastrostomy establishment of a new opening into the stomach or gastric fistula, is performed in cases in which the passage of food and liquids from the mouth to the stomach is arrested or rendered difficult. Gastrostomy should be resorted to: (1) In all cases of malignant disease of the esophagus, including the cardia, as soon as the dysphagia appears. (2) In cases in which inoperable tumors (struma, aneurisms, intrathoracic growths) compress the esophagus to such a degree that even liquid food cannot be taken by the patient in sufficient quantity to maintain nutrition even at a degree of bare subsistence. (3) In benign strictures of the esophagus in which all attempts to dilate them by the way of the mouth have failed. In this group after gastrostomy the retrograde dilatation of the stricture by way of the new gastric opening can often be successfully achieved. After the latter has been efficiently done the gastric fistula may again be closed. (4) In cases of idiopathic dilatation of the esophagus a gastric fistula may be temporarily established in order to introduce food into the stomach directly, and thus give the esophagus a chance to rest, recuperate, and contract. This, however, is not an absolute indication, as the same method of treatment can be carried out by nourishing the patient through a tube introduced by way of the mouth. Here, also, the esophagus is entirely at rest, as the food does not come in contact with it.

Measures to Facilitate the Outflow of Chyme from the Stomach: Divulsion of the pylorus; pyloroplasty; gastroenterostomy. These operations are performed in all cases in which the outflow from the pylorus is permanently retarded to such a degree that constant ischochymia results. Inasmuch as these conditions are quite frequent and their management is of much importance, it may be well to dwell on this subject a little longer. The outflow through the pylorus may be impaired by the followlowing agencies: (1) Narrowing of the lumen of the pylorus by benign strictures, by idiopathic hypertrophy, or by malignant tumors. (2) By spasmodic contraction of the pylorus in consequence of an ulcer in its immediate neighborhood. (3) Excessive dilatation of the stomach with radically impaired function of its muscular apparatus.

It is quite evident that pyloroplasty or divulsion of the pylorus will come into consideration only in the benign form of Group I. (*i. e.*, those subjects with benign stricture and hypertrophy of the pylorus), while in the remainder of the groups enumerated gastroenterostomy is demanded as the only feasible operation. Divulsion of the pylorus has not been practised within recent years, as recurrences of the stricture have often followed soon after this procedure. Although pyloroplasty is an ideal operation, since it creates anew an almost normal condition of the stomach and restores its function, it is not frequently performed. The conditions suitable for pyloroplasty are not numerous (only benign stricture and not too excessive hypertrophy of the pylorus), and even here it can be replaced by gastroenterostomy. This is the operation which is more often practised than any other surgical procedure on the stomach. It is the only operation practicable in malignant diseases involving the pylorus, in ulcer in the neighborhood or within this orifice, and, finally, in extreme atonic dilatation of the stomach.

Resection of part of the stomach or excision of the entire organ is performed in cases of malignant disease. The indication to remove malignant growths by surgical intervention is always present, but unfortunately not always feasible or possible. Cases adapted for partial resection of the stomach are those in which the tumor is confined to a certain part of the stomach, is quite circumscribed, and has not as yet involved the adjacent organs. If the pylorus is affected a pylorectomy is done with the performance of either a duodenogastrostomy or a plain gastroenterostomy after suturing the stomach and duodenum separately. A diffuse carcinoma extending over the entire surface of the stomach, but sharply terminating at the cardia and pylorus, may be removed by an entire excision of the stomach and the performance of an esophagoduodenostomy, provided there be no cancerous deposits in other organs nor adhesions of the growth to contiguous parts.

Gastrolysis, or loosening of adhesions from the stomach, is performed either in connection with other operations or in cases in which such adhesions cause persistent marked pains, and when their existence is recognized by distinct symptoms or after an exploratory laparotomy.

Gastroplication, folding and suturing the stomach walls to each other, has been advocated by Bircher and Weir in cases of dilatation of this organ. The operation may be indicated in excessive dilatation of the stomach without the presence of a stricture.

Gastropexy, suturing or fastening the stomach to the upper part of the abdominal wall, has been suggested by Duret as a remedy for gastroptosis and also Glénard's disease. From my own experience I must say that I have not as yet met a case of enteroptosis requiring such an operation.

Having discussed the indications for operations upon the stomach in a general way, it may be of interest to go a little more into detail with regard to surgical intervention for removing conditions of

ischochymia. For, numerically, it is for this condition that more than half of all the operations of the stomach are performed. From a clinical standpoint the large group of ischochymia must be divided into two classes: Firstly, cases of ischochymia due to benign processes (ulcer near or within the pylorus, cicatricial stenosis of the pylorus, idiopathic hypertrophy of the pylorus, extreme dilatation of the stomach due to atony of its muscular layer), and, secondly, cases due to malignant diseases of the stomach (cancer of the pylorus and also of the stomach).

Benign forms of ischochymia often show a tendency to amelioration, especially if the stenosis is not too far advanced. Here a rational dietetic treatment is crowned with good results. For this reason we should not be hasty in advocating surgical intervention. We should first try all the rational non-surgical methods of treatment at our command, and only if they absolutely fail and the ischochymia remains in a high degree (*i. e.*, persists even on a liquid-food diet), should we urgently recommend an operation. For, if the latter be omitted in the conditions just mentioned a fatal issue will sooner or later occur.

The operation should also be recommended in cases in which the attacks of ischochymia have appeared repeatedly or where an ulcer with considerable hemorrhage has preceded the existing trouble, and the patient is quite emaciated.

The reason why surgical intervention can not as yet be advised in all cases of more or less permanent ischochymia is the high mortality following operative intervention. In cases of ischochymia in my own practice, due to benign processes operated upon by the best surgeons of this city, there were six deaths among twenty cases, or a percentage of mortality of thirty. In Czerny's clinic the mortality of all operations upon the stomach gave the average figure of sixteen per cent. The mortality of these operations (gastroenterostomy or pyloroplasty) thus being so high we cannot advocate them in the benign form of ischochymia, unless a condition exists which is incompatible with life.

The other group of cases of ischochymia resulting from malignant disease of the stomach, and more especially of the pylorus,cannot materially improve by rational medical treatment. In most instances the ischochymia will progressively become worse and naturally increase the suffering and hasten death. An operation will be the only rational way of treating this group. Even the great mortality will not deter us from urging surgical aid. These patients are beyond help, and we must use all feasible methods of alleviating their suffering and prolonging life. As soon as the diagnosis of cancer of the stomach can be positively made, and there is a concomitant ischochymia, an operation (gastroenterostomy and perhaps also excision of the growth) should be performed in every case without any further delay.

In conclusion I beg to submit the following propositions:

1. Operations on the stomach for malignant disease should be performed as early as possible.

2. In benign affections operations on the stomach should be performed if all other curative means have been exhausted and have failed to produce relief.

20 East Sixty-third Street.

DISCUSSION.

Dr. DeLancey Rochester of Erie County said that for malignant tumors operation is of course the indication. The sooner it is done the better. Even a reasonably well-founded suspicion of the presence of malignant neoplasm will justify at least exploratory incision. In the case of benign tumors it is more difficult to decide. If there is not marked improvement within two months after treatment has been begun in a case in which there are severe digestive symptoms and in which the general nutrition is suffering a great deal, it is advisable to operate. Usually the trouble will be found at the pylorus in these cases; some form of contracture or hypertrophy being present. For such cases a pyloroplasty is better than a gastro-enterostomy. The connection with the intestine is apt to be made lower down than is intended and a considerable amount of intestinal digestive space is lost. Duodenal digestion at least is excluded and this is of importance.

Dr. Finder of Troy said that operations on the stomach should be undertaken more frequently than they are. The stomach stands operative interference much better than was anticipated by surgeons some time ago. He had seen five operations involving the stomach within the last year in his own neighborhood from all of which the patients recovered without incident. In one of the cases practically all of the stomach was removed. Relief can be afforded to gastric symptoms and patients can be relieved of a great deal of discomfort and given a reasonably good chance for their lives by boldly operating in severe cases. As a matter of fact it proves not to require so much boldness after all.

Dr. Marcy of Boston said that the day had certainly come when more operations will be done on the stomach than heretofore. We are learning that the surgeon has a distinct place in the treatment of chronic gastric symptoms from benign causes as well as from malignant neoplasms.

Dr. Einhorn, in closing the discussion, said that he would coincide with the suggestion as to operations for benign stomach affections, only that the mortality of operations on the stomach in such cases is as yet so high. After all the death-rate is nearly if not quite 25 per cent. and that in the hands of good operators. Even

patients who have not been exhausted by the disease and go to the operating-table reasonably well nourished die after operation. The medical man feels like treating such patients medically, until absolutely all hope of improvement seems past.

In reply to a question as to whether interference with the large plexuses of the abdominal sympathetic caused death in these cases, Dr. Einhorn said that while death is, of course, often due partly at least to shock and this might be supposed to be propagated through the sympathetic, actual interference with these plexuses so as to directly cause death has not been observed.

CLINICAL MEMORANDUM.

A CASE OF LOCOMOTOR ATAXIA BEGINNING IN THE SACRAL CORD AND PRESENTING UNUSUAL SENSORY SYMPTOMS.

BY CHARLES J. ALDRICH, M.D.,
OF CLEVELAND, OHIO;
LECTURER ON CLINICAL NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS; NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CLEVELAND CITY HOSPITAL.

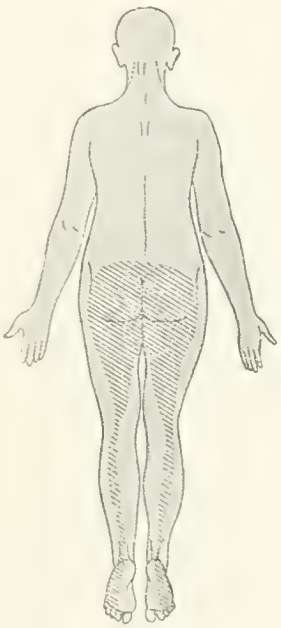
MRS. K. T., aged forty-seven years, white, widowed eleven years, United-States born, consulted me July 20, 1896, and gave the following history: Her father and mother both died of cerebral apoplexy between the years of sixty and seventy. Her several brothers and sisters are all strong, healthy people. She has never been sickly or weakly; on the contrary, has been a very healthy, hardy, hard-working woman. She has, however, suffered at intervals during the past seven years from severe headaches, accompanied by faintness and distressing spells of vomiting. She has never been pregnant, although her generative organs have seemed normal. She married twenty years ago. Fifteen years ago she contracted syphilis from her husband, who, eleven years since, died of syphilitic brain disease. Her primary manifestation consisted of multiple sores on the labiæ, which were not followed by secondaries, although she had six months' homeopathic treatment.

Three years ago she experienced some peculiar sensation in the rectum, which, she said, "Felt like a cannon-ball in my rectum which lay there dragging down my whole insides." She soon noticed some loss of control of the rectal and vesical sphincters, and later a decided unsteadiness of gait and posture, especially while in the dark or with the eyes covered as in the act of washing the face. At about this time she developed a peculiar sensitiveness of the skin to hot and cold water. Her bath, or in fact the contact of any object that could be said to have a temperature above or below that which the skin recognizes as normal, produced, not the former natural sensation, but a decided sensation of pain, that was slight or intense according as the water was warm or hot, cool or cold. This sensitiveness or perverted sensation of the skin was so great that the most careful regulation of the temperature of her bath failed to prevent the disagreeably painful effects of contact with water. This disordered sensory appreciation was general, but was less marked on the face. She also noticed that the skin over the buttocks, down the back of the thighs, about the anus, and the lower part of the vulva was insentient to touch. In this region she suffered from true fulgurant pains.

One year later, while combing her hair before a mirror, she was shocked to discover that she was totally blind in the left eye. She had experienced no other ocular symptoms.

She has suffered from laryngeal crises, especially as she was passing into sleep, which have been so severe at times as to threaten suffocation. All of these symptoms have gradually disappeared up to the present time, July 20, 1896, when she called to see me in reference to a pelvic tumor which she supposed was the cause of all her troubles.

FIG. 1.



The double shading shows the area of tactile anesthesia on first examination; the single lines show the area of the hypercryalgesia (or painful sensation to moderate degrees of cold), and hyperthermalgesia (painful sensation to moderate degrees of heat).

Examination.—She is an intelligent, well-nourished, good-looking woman, bearing her years well, and possessing good muscular power. Her gait is ataxic, posture poor, both knee-jerks absent, plantar, epigastric, pupillary, skin and pharyngeal reflexes all absent. Localizing power is diminished and sense of deep pressure is sensibly lessened. Muscular incoordination is present in all four extremities, but is less marked in the arms than the lower members.

She is markedly analgesic over the skin of the feet and the legs; calls a smart prick of a pin "your finger." This analgesia fades and disappears above the line of the ilia. She feels a light touch on the inside of the soles of the feet, but the outside of the soles are insensitive to pain and touch. A narrow line of tactile anesthesia extends upward on the back and the outside of the legs to join the

apices of the large saddle-shaped area of tactile anesthesia that covers the buttocks, as shown in the figure. The labiæ and inside of the vagina, urethra, and rectum are insensible to touch. She feels neither feces nor urine as they pass. The region about the clitoris is sentient, and she confesses to sexual desire.

The entire integument of the body and the mucous membranes of the mouth, nose, und vagina were particularly sensitive to the application of anything moderately warm or cold. Test tubes filled with water at any temperature between 115° F. and 60° F. were recognized as painful impressions only. If the temperature was above 115° F. she recognized it as hot; if it was below 60° F. it was called cold. If the temperature of the tubes was anywhere from 92° F. to 96° F. they were recognized as touch. So sensitive was the skin to temperature that, with the exception of the few and last-named neutral degrees that were felt as touch, any temperature between 60° F. and 115° F. was shrunk from and declared to be painful, *although its temperature character was unrecognized.* Temperature so hot as to be slightly painful but bearable by the skin of a normal person, brought screams from her, yet she assured me that it was not the pain of a burn, but "just a pain." When an ice-filled tube was brought in contact with her skin she cried out loudly, and sprang from the table. Questions elicited the statement that it was not the excess of cold but the electric sort of pain that caused her to shrink and cry out. Careful experiment, oft repeated, confirmed these findings, and the fact that her pain was proportionate to any departure above or below the nineties of the Fahrenheit scale.

Careful examination of the eyes reveals some interesting facts. Both pupils are absolutely inactive to the stimulus of light. While both eyes are uncovered they react to efforts of accommodation. Looking at a near object produces an over-action of the left internal rectus that turns the blind eye inward. Before she lost the sight of this eye she never had double vision. Unable to find any change in the disc that could be compared with gray atrophy, I asked Drs. Baker and Shackleton to examine the discs, and they reported no atrophy nor any discernible cause for her blindness. The pupils respond to mydriatics, but the left less readily than the right. The field of the right eye was contracted to neither form nor color, and its disc was normal.

Examination of the pelvic organs revealed an apparently normal uterus and adnexa. Seemingly attached to, and filling the right iliac fossa, was an immovable mass, feeling solid to the touch, perhaps a degenerated and calcified fibroid, but it was certainly not pressing on any of the large nerve trunks in such a way as to cause any, much less all, of her symptoms. Drs. Rossenwasser and Spurney examined her, and confirmed the opinion as to the absolute lack of relation between the tumor and the above described symptoms.

Like all such people who have some lesion or disease that with their limited knowledge is recognizable, she doubted my assurances that she was suffering from a disease of the spinal cord, and that her tumor had absolutely nothing to do with her disabilities, so she started the rounds to secure an opinion that coincided with her own and that included the tumor. Unfortunately she found such a person. She was assured that anyone ought to know that it was the pressure of the tumor on the spinal nerves that destroyed her sphincter control and interfered with her locomotion.

She was taken to a hospital, and the tumor, uterus, and ovaries were removed *per vaginum* by a homeopathic expert from Buffalo, who has since assured her *that he was never told that she had locomotor ataxia.* She recovered from the "very successful" operation in due season, and then returned to me for relief from a very distressing lot of symptoms that appeared at the time of her previous regular menstruation. Flushes, perspirations, etc., were not a dot to what her suddenly acquired menopause brought her in the form of fits of melancholia, real mania, and finally genuine epileptic spasms. Treatment has somewhat ameliorated the latter condition, but she became so violent a short time ago that she was arrested on an insanity warrant and sent to the State Hospital, from which she was transferred to the City Hospital.

April 13, 1897, I examined her, and found that she was completely insensible to a pin-prick over the entire integument except the eyelids; that loss of sensation to touch was general but less marked on the face and on the inside of the arms and forearms; that the disturbed sensation to temperature was practically the same; that the sensation of a cannon-ball in the rectum was the same, and that she then had lightning pains in the lower limbs.

October 20, 1897. I have learned by careful experiment that she can judge temperatures better than before; that her analgesia is now complete in both skin and mucous membranes; that she still has the lightning pains in the lower limbs; that she is more incoordinate in all her members, the increase being most marked in the arms; that because of a general and almost complete tactile anesthesia it is no longer possible to note the peculiar distribution that was so interesting on our first examination, and that her eye now presents a typical gray atrophy.

The apology for occupying so much space with a detailed report of this case is the extreme rarity of its clinical phenomena.

First. This is seen in its evident beginning in the sacral cord, as shown by the "cannon-ball" sensation; early loss of sphincter control and early occurrence of fulminating pains in the perineum and over the area of tactile anesthesia.

The rarity of tabes beginning in the sacral cord is evidenced by the fact that it is unmentioned by Hammond, Gower, Erb, Ross, Church, Leyden, Spitzka, and Hirt. Peterson[1] and Starr merely mention it as a rarity. Peterson[2] in referring to its occurrence compares its rarity to that of the cervical type. Of the latter I know of but two cases that have been reported in the United States,[3-4] and it is scarcely mentioned by foreign authors, once by Charcot[5] and once in Vulpian's "Maladies du Système Nerveaux." I am led to believe the sacral type very rare,

as I have been unable to find any reports of it other than those mentioned.*

That this is not a case of secondary tabes resulting from syphilitic meningitis, or new formation, or tumor pressing on the sacral segments, is shown by the lack of paralysis of the flexors of the ankles and toes and small muscles of the feet, and the irregular and erratic occurrence of the pains in the anesthetic areas.

Second. The disturbances of sensation are both unusual and remarkable. To Hitzig[6] is due the credit of calling our attention to the tactile anesthesia of the trunk in tabes. Laehr[7] has made by far the most exact and extensive study of this symptom. Patrick[8] and Burr[9] have recently contributed some very interesting and valuable observations on this hitherto little-noticed phenomenon. But in the publications of none of these authors or elsewhere can I learn of any case of the sacral type being studied in reference to trunk anesthesia,† and I believe this to be the first recorded instance of the anesthesia taking the saddle-shape of a lesion of the last segments of the cord. The rapid extension of the tactile anesthesia until it became general in sixteen months is rare and interesting. Complete analgesia is also extremely rare.[10]

The disordered appreciation of temperature is unique. Starr[11] claims priority in calling attention to this extreme sensitiveness to heat and cold as a symptom of tabes, and designates the sensitiveness to heat, *hyperthermalgesia*, and to cold, *hypercryalgesia*. According to him, the ability to appreciate the quality of temperature is not lacking, but the lack of quantity appreciation only. If the latter statement does him justice his nomenclature is wrong, and he is entitled to no credit, as Rosenthal,[12] Donath, and others have called attention to cases where the quantity of the temperature was misjudged, and the skin was hyperesthetic to a moderate degree of heat or cold. The terms used by some authors—*hypercyresthesia* and *hyperthermesthesia*—meaning respectively an oversensitiveness to cold and heat, correctly describe the symptoms put forward by Starr as new symptoms of tabes. In my case, however, the application of moderate degrees of heat or cold within certain stated limits produced *actual pain without its quality of heat or cold being recognized.*

To this condition it is proper to apply the names which Starr has proposed to designate conditions of the skin, wherein a painful sensation is produced by the contact of objects moderately hot or cold. At my last examination I learned that she was able to differentiate temperatures with much greater accuracy than before. It would be interesting to know if there has been an actual bettering of her temperature sense, or, as is more probable, an education of the nerves of the skin to differentiate by associating one kind of pain with heat and another with cold.

Third. The association of gastric with laryngeal crises, is unusual, although not to be compared with the rarity of crises of the clitoris which existed in this case. The patient confessed to having "spells" of most intense sexual excitement, accompanied by voluptuous sensations. She was very much distressed about these spells, and asked me if they were in any way connected with her disease. In the literature of tabes I have but once noticed this form of crises, and that by Eichorst, who quotes Pitres.[13]

Fourth. The fulgurating pains occurring in the areas of tactile anesthesia constitute an *anesthesia dolorosa*. Spitzka, Starr,[14] and others refer to the occurrence of fulgurating pains in the perineum, but I am unable to find any reference to their being largely confined to the anesthetic area.

Fifth. Dana[15] calls attention to the left eye being most frequently the first to be attacked by optic atrophy, and Knies[16] mentions the fact that one eye may be affected years before its fellow, but I am unable to find anything in the literature of tabes referring to a sudden loss of sight and no atrophy discernible one year later.

Sixth. The useless, cruel, and unnecessary operation performed on this poor woman by a more ambitious than learned gynecologist demonstrates the possibility of a tabetic, in the ataxic and paralytic stage, to undergo and recover from a capital operation as well as a normal person.

I have also been much interested in noting no apparent increase or diminution in the rapidity of the progress of the spinal symptoms since the operation, but have been pained to see a rapid advance of mental derangement result, as I believe, from the sudden and unnatural establishment of the menopause.

744 PROSPECT STREET.

* Since the above was written I have learned that Pineles (*Arbeiten aus dem Institut für Anatomie u. Physiologie*, etc., vol. iv.) has studied, clinically and pathologically, a case of tabes of the sacral cord.

† Hirt, "Diseases of the Nervous System," p. 646, mentions a case of tabes with a saddle-shaped area of anesthesia on the buttocks and extending down the thighs.

Christian Scientists in Jail.—A number of Christian Scientists at Americus, Ga., who refused to be vaccinated, were sentenced on November 17th by the Mayor's Court to terms of from fifteen to thirty days, and to pay fines of from $3 to $15.

MEDICAL PROGRESS.

An Application to Shorten the Period of Desquamation in Scarlet Fever.—WILLIAMS (*Boston Med. and Surg. Jour.*, September 14, 1899) advises an application to the skin of patients suffering from scarlet fever, in order to prevent the spread of the scales of epidermis which are supposed in part to disseminate the disease. For this purpose he recommends a mixture of 1 part of glycerin to 7 parts of a 15 volume solution of hydrogen dioxid. The latter should contain a little free hydrochloric acid. If the amount is very small some may be added but the mixture should not contain more than one-tenth of 1 per cent. of the acid. This mixture should be rubbed daily all over the patient except in the hair. If properly carried out the period of desquamation is shortened more than three days and the patient's stay in the hospital or in an isolating-chamber is reduced to that extent.

Objections to Certain Methods for the Reduction of Dislocation at the Shoulder Joint.—THOMAS (*Liverpool Med. Chir. Jour.*, July, 1899) has seen a large number of patients who have exhibited loss of power and loss of sensation in the arm following the reduction of a dislocation of the humerus. The musculo-spiral nerve was the most often involved, then the circumflex, ulner, and median. In every instance the patient was certain that the grasp of the hand before the operation was unimpaired. The author has never seen paralysis follow any other method of reduction than that with the foot in the axilla. In this method the nerves are forcibly compressed against the head of the humerus. Other accidents which may occur with this method of reduction are fracture of the ribs, fracture of the humerus, and damage to the vessels. A method of reduction similar to that of Kocher which is applicable in any form of dislocation consists in placing the patient upon a chair while the scapula is fixed by an assistant who stands on the opposite side of the patient and grasps the outer end of the clavicle with one hand and the axillary border of the scapula with the other. The surgeon grasps the patient's wrist with one hand and the lower end of the humerus with the other and quietly and slowly abducts the arm to a right angle with the body. Traction and outward rotation are commenced when the humerus is half way up. If the bone does not return to its proper position, traction is increased and the humerus may be slowly rocked from side to side or up and down. When the reduction is effected the arm is rotated inward and placed across the chest with the hand upon the sound shoulder. If the procedure is carried out slowly the pain is so slight that chloroform is rarely required.

Prevention and Cure of Ventral Hernia.—SMITH (*Lancet*, July 29, 1899) believes that ventral hernia after laparotomy is quite preventable. If allowed to develop it sometimes causes more trouble than the condition for which laparotomy was performed, and it also prevents other patients from undergoing operation through dread of a similar mishap. The measures for its prevention are: (*a*) leaving in the stitches a month if the patient is thin enough to allow the use of a through-and-through stitch; (*b*) using non-absorbable buried sutures when the patient is fat enough to require two layers of ligatures; (*c*) discarding the abdominal drainage-tube after pelvic operations and, when necessary, draining by the vagina; (*d*) securing accurate coaptation of the cut edges by marking the places where the stitches are to go before the incision is made; (*e*) taking care that no peritoneum is curved up so as to come between the muscle and fascia of opposite sides. Hernia can be cured if slight with a single buried silkwormgut purse-string suture. In larger cases the edges of the ring should be split until the recti muscles are exposed from top to bottom. These should be sutured with buried silkworm-gut.

THERAPEUTIC NOTES.

Treatment of Gonorrhea as Carried Out in a Military Hospital During the Last Sixteen Years.—VOGL (*Münch. Med. Woch.*, August 1, 1899) reviews the different forms of treatment of gonorrhea which have been carried out in the military hospital at Munich since 1882. They include all those methods which are still in vogue as well as some which have been given up. Among the discarded remedies may be mentioned hydrochinon, iodoform, thalin, zinc, and sozoidolicum. Some of these were found useless, while others had a direct injurious effect. Later the opinion obtained ground that the character of the injection was indifferent so long as it was made in the right way. In the year 1893 the principles of Neisser were taken up and patients were treated by injections of solutions of nitrate of silver 1 to 5000. In the next year permanganate of potash, 1 to 4000, and zinc sulphocarbolate, 1 to 180, were tried. In the following year about 200 patients were treated with nitrate of silver of a strength of 1 to 3000, while ice-bags were applied if there was an excessive degree of inflammation. In the year 1897 36 patients were treated with protargol, and the results of treatment when begun sufficiently early were quite satisfactory. Looking back over the records of this long period, the author finds that the average duration of treatment in the days before the use of specific antigonorrheal remedies was about forty-five days. After the introduction of injections of nitrate of silver the average duration was forty-five to forty-seven days. Niessen, who was in charge of the hospital in 1896 and 1897, and who treated patients with various silver salts, reported an average duration of treatment of only forty days, but he discharged twenty men as not cured. In the following year, when the patients were treated with nitrate of silver, potash permanganate, and later with protargol, the average duration of treatment was forty-two days, but seven men were discharged uncured. In the light of these statistics the newer remedies do not seem to be much of an improvement over the older plan of hygienic and dietetic treatment—absolute rest, milk diet, and the application of cold in the acute stages. The duration of gonorrhea depends for the most part upon the condition of the individual who has been infected. It is certain that the specific remedies have failed to fulfil the hopes of their early advocates.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 25, 1899.

THE PLAGUE AND OUR LESSER PORTS.

WE have insisted over and over again during the last four months, ever since assurance came of existence of genuine bubonic plague at Oporto, that the disease would surely find its way to this country. It has reached New York Harbor. Let us hope that it will not find its way into some less guarded port. That is the danger and it is a serious one. The disease is now in the track of commerce at more points than are perhaps imagined. At least one other vessel from Santos, an Austrian Lloyd steamer bound for a Mediterranean port, reported toward the close of last week that the disease had broken out on board and death had occurred. Rio de Janeiro in Brazil is also infected with the disease and is liable to export it.

Very little has been said recently about the plague at Asuncion. A correspondent who is in close relations with that part of South America has a letter in our columns this week from which it is clear that the disease has probably gained a firm hold in that unsanitary city. None of the South-American seaports are in a position to defend themselves effectually against the importation of the disease and all of them are in such an unsanitary state that it will be next to impossible to eradicate the disease once it has gained an entrance. We may look in the next few weeks for reports of the occurrence of the disease at many other South-American ports besides those already affected. The plague has reached the American continent to stay at least for months.

Under present conditions the danger of the plague invading the United States through the large ports of entry is not very great. Quarantine regulations are too stringent and are too strictly enforced to allow this, beside quarantine officials have been put on their mettle by the urgency of the danger. At the lesser ports, however, the possibility of entrance of the disease can not be excluded with such ready assurance. It is through unimportant commercial ports, where it was least expected that the plague has forced its way in the present epidemic. Oporto is of very little importance in Europe. Asuncion is so far from the coast in South America that the report of plague there seemed absurd on the face of it. Santos is by no means the most important port of Brazil. There is more and more reason in the present situation for the warning we have sounded before, "Guard our lesser ports."

GALL-STONE SURGERY—A PROSPECT—A WARNING.

THE recent presentation of the surgery of the gall-bladder, in the paper of Dr. Maurice Richardson of Boston, before the Section on Surgery of the New York Academy of Medicine (see page 698 of this issue) elicited an unusually instructive discussion. It was participated in by men whose practical experience in this line of work most entitles them to speak with authority on this subject. The paper included in its scope all the biliary apparatus beyond the absolute confines of the liver, and the discussion was equally wide.

In reviewing, about this time last year, Professor Kehr's work on the surgery of gall-stones, we said that this subject was rapidly claiming a most important place in the attention of the general surgeon. Already statistics show that five times as many operations are being done upon the biliary passages as were being recorded five years ago. The day of palliative medicine for gall-stones is rapidly passing.

Each renewed attack that is allowed to occur in any individual case, besides presenting certain very definite actual dangers to life, is, unfortunately, complicating the field of the probably inevitable operation. To echo Dr. Richardson, "Nature is a poor operator in these cases; what the surgeon can accomplish in a few minutes of clean-cut work with the knife she takes years to do, and then does not always do it satisfactorily or even successfully."

An operation upon the biliary tract is always a serious procedure, and in cases in which active pathological processes have been at work during many years' experience has shown that what may be called primary operations for gall-stones, that is, during the early period of their presence, have very little danger in them. The conclusion is self-evident and the surgeons are acting accordingly.

As to the dangers of the operation, hemorrhage was insisted on at this meeting by men of the widest experience as perhaps the most serious complication. Hemorrhage from large vessels is not to be feared so much as a persistent capillary oozing. Murphy of Chicago thinks this tendency to bleed is due to the jaundice, and relieves this condition before operating further. Curtis noted it especially in a case of beginning cirrhosis of the liver, and attributes it to the obstruction to the portal circulation caused by the sclerotic changes in that organ. Malignant disease in the tissues undoubtedly favors bleeding. These are factors that must be borne in mind; and in addition thereto any and every manipulation beyond those absolutely necessary to accomplish the relief for which the operation is undertaken must perforce be avoided. Ideally complete operations are not adapted to the present stage of operative procedures on the bile passages.

The experience of the Boston surgeons is quoted as distrusting completely the closure of the gall-bladder and of the abdominal wall above it, even in simple uncomplicated cases of gall-stones. Suture of the bile-ducts has proved equally unsatisfactory in a number of hands. Incision, removal of the stones and drainage have so far given the best results.

One of the most important features of the discussion is the consensus of opinion that gall-stones may cause an induration of tissues and a tense distention of the gall-bladder that may very deceptively simulate maglignant disease in this region. An exploratory incision under these circumstances is counseled by all. Even after the opening of the abdomen, gross appearances must not be allowed to preclude surgical procedures if any measure of relief can be afforded the patient. Often it will be found that after such relief, the appearances of malignancy subside and seemingly complete recovery occurs.

Everything in the present aspect of gall-stone surgery encourges the idea that early operative intervention in these pitiable cases is destined to confer a boon on suffering humanity. There is the danger that as in the case of the uterus and adnexa, may we say also the appendix, a certain furor operandi will lead to unnecessary operative interference, to too extensive dissection, to mistakes of diagnosis due to statistical anxiety, to fatalities that are unjustified. The sad experience of too much operating in gynecology and of excessive appendectomy may serve as a warning in this new branch of surgery that is just entering upon its modern development.

ECHOES AND NEWS.

The Automobile in Practice.—An English medical man has driven his "motor-car" 5000 miles in a year, at a total running expense of $130.

First Woman Doctor in Germany.—Agnes Nacker is the first woman doctor admitted to general practice in Germany. She resides in Berlin. It has taken the Prussian Cabinet two years to decide her case.

Dengue Fever in Manila.—Major Woodhull, Chief Surgeon at Manila, has reported that "a sharp and quite general epidemic of dengue has prevailed in Luzon for some months past, and it appears to be spreading to the south.

Snake-bite in India.—Nearly 22,000 deaths from snake-bite were recorded in India in 1898. The efficiency of the new serum is now fairly well established, but the price of a dose—$1—puts it beyond the reach of most of the victims.

Surgeon Wilkinson Going to Manila.—Acting Assistant Surgeon H. Brockman Wilkinson, United States Army was ordered, upon the recommendation of the surgeon-general, to accompany the Forty-first Infantry, United States Volunteers, on the transport "Logan," which sailed on November 19th for the Philippines.

The Health of Immigrants.—The Bureau of Immigration at Washington is preparing plans for a more rigid examination of intending immigrants. The way in which these people are examined by medical officers abroad has

been investigated by officials of the bureau, and it has been found that in many cases the examination is a farce.

Medico-legal Department in Manila.—General Otis has established a medico-legal department in Manila in charge of two Filipino physicians, Drs. José R. Hidalgo and Gregorio Singlan. An emergency ward and dissecting-room have also been established. The department is to be subject to the orders of the Supreme Court and the tribunals of justice in the city of Manila.

The Southern Surgical and Gynecological Association.—The twelfth annual meeting of this association will be held at the St. Charles Hotel, New Orleans, La., on December 5, 6, and 7, 1899. The program is of unusual interest, covering a large range of surgical subjects. Out of forty-three numbers on the program all but six treat of surgical conditions. St. Charles Hotel will be the headquarters for the association. Reduced railroad rates have been secured.

Officers of the New York State Association of Railway Surgeons.—At the ninth annual meeting of this association which was held at the Academy of Medicine Thursday, November 16, 1899, the following officers were elected for the ensuing year: President, Dr. J. L. Eddy, Olean, New York; vice-president, Dr. W. R. Townsend, New York City; second vice-president, Dr. A. P. Jack, Canisteo, N. Y.; treasurer, Dr. P. D. Mills, Middletown, N. Y.; secretary, Dr. C. B. Herrick, Troy, N.Y. (re-elected). An account of the proceedings of the meeting, which was a very successful one, will be published in a subsequent issue of the MEDICAL NEWS.

Enthusiasm of English Women for Positions as Army Nurses.—The nursing corps is inundated with applications not merely from nurses but from scores and hundreds of women from private life, including numbers of officers' wives and daughters and society women of prominence. The War Department has, however, very wisely and politely explained that it cannot consider these offers from volunteers having had no previous experience in nursing, however grateful it is for the patriotism implied by their willingness, until the supply of trained material is exhausted. And as the Army Medical Service has a reserve of retired nurses similar to that of the fighting strength there is a considerable amount of trained available supply still unused. Numbers of the applications from trained nurses have had to be declined, or at least postponed, on account of nurses having had special military experience.

Sir William MacCormac's Duties as Military Surgeon.—Whatever title of military command may be conferred upon Sir William MacCormac in his new capacity as military surgeon, it will be found to be no mere honorary designation, for the Army Medical Corps for South Africa alone, including bearers, dressers, hospital attendants and the like, reaches the imposing total of nearly 2300 members, practically two regiments of these soldiers of peace. In addition to these there will be the nursing staff which has a present strength of over fifty and will be brought up to nearly one hundred, and a nearly equal number of native hospital orderlies accompanying the Indian troops. The patriotic example of the president of the Royal College of Surgeons has already borne even more fruit than anticipated, as one hears on all hands the willingness expressed by members of the medical profession of all degrees of prominence and occupation to volunteer for service in South Africa.

Loveliness.—This is the name of a little book written by Elizabeth Stuart Phelps, in which are depicted the experiences of a little girl and a little dog. The dog has been christened by the extravagantly sentimental name of Loveliness. The little girl is greatly attached to the little dog and the little dog evidently reciprocates the affection. The little dog suddenly disappears; has been stolen by a tramp. The little girl thereupon begins forthwith to pine away almost to the point of death. At this juncture the little dog is rescued from the hands of an experimenter in physiology at a laboratory where he is about to contribute the greatest benefit to mankind that it falls to the good lot of a dog to contribute. The little girl and the little dog both get well and live together happily ever after. The book was evidently designed as a sentimental appeal to the delicate sensibilities of our antivivisectionist friends. The little book will probably not do any harm or any good. For the sake of saving one life the little dog missed the opportunity of his life—of contributing what he could for the rescue of tens of thousands quite as precious little girls from untimely graves.

The Management of the Public Hospitals at St. Louis.—An ordinance is under consideration by the municipal assembly of St. Louis providing for the management of the city hospitals by creating a "Visiting Hospital Staff" which shall constitute a board of hospital administration. The Visiting Hospital Staff shall be appointed by the Health Commissioner, subject to the approval of the Board of Health. The members of this staff shall be reputable practising physicians, and selected from the faculties of the various medical schools of the city in proportion to the medical students of each. One section or subcommittee of the visiting staff shall visit each of the hospitals of the city daily during a definite part of the year. Said visiting hospital staff, with the co-operation of the resident staff of internes, shall have the entire responsibility for the treatment of all patients who shall be assigned to the care of the members of the hospital staff of each school according to the number of students, unless the patient expresses a preference for some particular school. It shall be the duty of the board to provide for and to conduct clinical instruction at the hospital for the benefit of medical college students, apportioning such work, as to instructors and hours, according to the number of students in each school. Clinical instruction at the hospital shall be open to all licensed physicians and stu

dents of reputable medical colleges on payment of $5.00 per year.

Liberal Salary for English Consultant Army Surgeons.—It will be gratifying to the self-respect of the profession to learn that the leading consultants, who have upon invitation volunteered for service in South Africa, Sir William MacCormac and Mr. Frederick Treves have been placed upon a salary proportionate to their rank both in the Army and in medical circles. The sum of $25,000 per annum with allowances for horse and other expenses, although in no sense an equivalent of the income actually sacrificed by these gentlemen, is still a significant and grateful proof of the importance attached to their services by the Army authorities. The high sense of duty which led to the volunteering of Mr. Treves, who, we are informed, was urgently invited to undertake the post by the War Office, will be even more highly appreciated by the profession when it is remembered that scarcely six months have elapsed since he resigned his teaching position at the London Hospital on account of the pressure of his enormous operative private practice.

The third consulting surgeon, Mr. G. H. Makins, although less widely known to the American profession, has a high standing among his confrères in London and is one of the leading surgeons at St. Thomas' Hospital. As Sir William MacCormac is also on the staff of the same hospital, it was probably his knowledge of Mr. Makins' sterling qualities which led to his selection. The students of St. Thomas' Hospital School, naturally greatly elated at the double honor conferred upon their college, gave both these gentlemen a most enthusiastic farewell ovation at Waterloo Station.

Surgeon-General Sternberg's Annual Report.—The annual report of Surgeon-General Sternberg of the Army has been made public. General Sternberg considers that "in times of peace we should prepare for war." This preparation should include a corps of trained medical officers larger than is absolutely necessary for the army on a peace basis, and systematic instruction in military medicine and hygiene for the medical officers of the National Guard as well as for those of the regular army; also, instruction of line officers in the elements of hygiene, and especially in camp sanitation. It should also include the establishment of camping-grounds in various parts of the country having an ample supply of pure water, a proper system of sewers, etc. If our volunteers, states Dr. Sternberg, could have been assembled in such camps during the late war a saving in lives and money would have resulted which would, without doubt, have demonstrated the economy of such preparation for war in time of peace. The number of deaths, including the regulars and volunteers from May 1, 1898, to June 30, 1899, is given as 6619. Of these 496 men were killed in battle, and 216 by accident, 202 died from gunshot wounds, 2774 from typhoid fever, 476 from malarial fever, 359 from pneumonia, 342 from diarrhea and dysentery, and 185 from yellow fever. General Sternberg attributes the prevalence of typhoid fever to the unsanitary condition of many of the camps where the disease became epidemic, and the failure to suppress the disease to the inexperience of regimental and line officers and the want of discipline among the men. General Sternberg does not consider a change in the ration among the men necessary. Dr. Seaman, however, maintains its utter inappropriateness in the Philippines.

The Plague Situation has all at once become of the deepest interest to us here in the United States from the appearance at the Quarantine Station of New York harbor of a vessel from Santos, Brazil, with cases of the disease on board. One death from bubonic plague occurred while the steamer was on its way North, and two persons, the captain and cook, were sick with the disease when the ship arrived. There is no danger, according to the quarantine authorities, of the disease reaching the city itself. The passengers and crew will be kept under observation until all danger is past, and the cargo will only be landed after the most careful precautions. Another vessel sailing from Santos, the Austrian Lloyd steamer "Berenice," bound for Triest, Austria, reported, when it touched at the Cape Verde Islands toward the end of last week, that plague had broken out on board, and that three of those attacked had died. At Santos itself the disease continues to spread, and the sanitary condition of the town is so defective that little hope exists of getting the disease under control for some time at least. Bubonic plague undoubtedly exists now also in the suburbs of Rio de Janeiro, and in the filthier parts of the town itself. At Asuncion, in Uruguay, the disease continues to spread. A correspondent this week gives a good idea of the hopeless state of affairs there. At Oporto from three to five new cases a day are being reported. Last week the director of the bacteriological institute of the city, Dr. Camara Pestana, died of the plague. He contracted the disease either while attending patients striken with the disease or while making bacteriologic investigations on the plague bacillus. The Government of Portugal is being aroused at last to a realization of the awful significance of the situation. One day last week the king of Portugal, King Charles, visited the plague hospital in order to encourage the sufferers and restore the courage of the populace, who now begin to fear the disease very much.

MEDICAL MATTERS IN NEW YORK.

MORE NURSES FOR THE "MAINE"—DIVISIONS BY THE HEALTH BOARD—A CASE OF ANTHRAX—TOOK POISON AS MEDICINE—WOMAN'S COMPLAINT AT BELLEVUE—PRESERVATIVES IN BEER—APPEAL FOR HOSPITAL WORK—ATTEMPTED TENEMENT-HOUSE REFORM.

AMONG the passengers who sailed on November 20th to join the hospital ship "Maine" were Dr. Hastings and twenty-nine dispensers, orderlies, and men nurses.

The Health Board has divided the Borough of Brooklyn into eleven hospital districts, and has promulgated a set of rules for more efficient operation of the ambulance service.

Philip Cooney, a 'longshoreman, died in the Long

Island College Hospital on November 14th of anthrax. The microscope established the diagnosis. Cooney had been at work in a warehouse on the East River front, handling hides, grain and hay. He had had a scratch in his neck, and no doubt this was the point of inoculation.

A young woman nearly lost her life on November 18th by swallowing carbolic acid in place of a tonic which she had been taking. It was a case of mistaking one bottle for another. Legislation requiring that poisons be dispensed in corrugated bottles would go far toward preventing such accidents.

William Graham went to Bellevue on November 15th and asked to be placed in the alcoholic ward. His request was granted, but there being thirty patients and but twenty-eight beds in the ward, he was told to "double-up" with another patient. This he refused to do. Instead he left the hospital, went home and committed suicide by cutting his throat. His wife complained bitterly that if he had been detained at Bellevue this would not have happened. It was, however, explained to her by Dr. Richards that her husband was not forced to leave the hospital, but as a voluntary patient he could not be compelled to stay.

At the meeting of the Special United States Senate Committee on Manufactures, of which Senator William E. Mason of Illinois, is chairman, held on November 13th at the Imperial Hotel, Max Schwarz, consulting brewer and director of the Brewers' Academy, recommended the use of preservatives in beer made for export, and said that those now used were not harmful. He declared that one-half ounce of salicylic acid to a barrel of beer was sometimes used, and that he had found bisulphate of lime in English beers, and a trace of sulphurous acid in some American products. He said that the Pasteur method of boiling the beer in bottles was not a reliable preventative of secondary fermentation. He had plenty of colleagues present to sustain his statements.

At a meeting of the Trustees of the Hospital Saturday and Sunday Association held on November 14th in the Charities' building, the General Agent reported upon the preparatory work for the coming collection in the churches, synagogues, trades and exchanges. The work is well advanced, and it is anticipated that the collection, which was over $70,000 last year, will, under the impulse of prosperity, reach a total of $100,000 this year. The money collected through this association is distributed on the basis of the number of days of free treatment given by each hospital to the needy poor. According to the last report of these hospitals to the association, they cared for 34,740 patients, of whom 21,052 were free patients unable to pay anything. In addition to this free-bed service, the associated hospitals gave treatment to 300,995 out-door or dispensary patients.

It is clearly set forth in the report of the Central Council of the Charity Organization Society for the year ending June 30, 1899, that the brief submitted to the Building Code Commission by the Tenement-house Committee of the Society has been utterly disregarded by the Commission. The brief contained fifteen definite recommendations, each accompanied by a statement setting forth the reasons for the recommendation and the advantages to be gained by its adoption. The result of their adoption would have been increased light and air, secured by large air-shafts, increased protection against fire, the supply of bathing facilities, and other changes, all intended to be conducive to the welfare and the health of the poor of this city. The Building Code Commission will not permit such changes to be made, although the press, the philanthrophic societies, the architects, and all good citizens approve them. A tenement-house exhibition will be held early in 1900.

The Health Department submits the following report of contagious diseases for the week ending November 18, 1899: Measles, 248 cases, and 12 deaths; diphtheria, 274 cases, and 46 deaths; laryngeal diphtheria (croup), 15 cases, and 9 deaths; scarlet fever, 136 cases, and 10 deaths; chicken-pox, 19 cases; tuberculosis, 125 cases, and 151 deaths; typhoid fever, 67 cases, and 22 deaths; cerebrospinal meningitis, 2 deaths.

MEDICAL MATTERS IN PHILADELPHIA.

[From Our Special Correspondent.]

COINCIDENT MALARIA AND ENTERIC FEVER—GRAVE CHARGES OF BRIBERY IN THE STATE BOARD EXAMINATIONS—PROSECUTION OF "OLEO" DEALERS—ADDITIONAL MEDICAL INSPECTORS TO BE APPOINTED—A DEATH FROM ACCIDENT IN THE HOT-AIR TREATMENT—LARGE ENDOWMENT FOR THE EPISCOPAL HOSPITAL—DR. JOHN B. DEAVER'S RESIGNATION FROM THE PHILADELPHIA HOSPITAL—DEATH OF DR. ALBERT FRICKE—MUTUAL-AID SOCIETY'S ELECTION OF OFFICERS.

PHILADELPHIA, November 18, 1899.

AN undoubted instance of concurrent enteric fever and malarial infection in the same patient was reported by Dr. J. Dutton Steele at the last meeting of the Section on General Medicine of the College of Physicians of Philadelphia, held November 13th. The patient, a man twenty-three years of age, first came under observation on the fourth day of the disease, presenting typical symptoms of typhoid, and such corroborative signs as splenic enlargement, rose-spots, prompt reaction to the serum-test, and a positive diazo-reaction. On the 21st day of the illness crisis occurred, the patient having a vigorous rigor, with a rise of temperature to 104° F. Six hours after the chill the patient's blood was examined, and a few hyalin and slightly pigmented, intracellular, tertian malarial parasites were found; the enlargement of the spleen became much more striking after the chill. Under appropriate treatment with quinin the patient made an uneventful recovery. Dr. Steele drew attention to the very pertinent fact stated by the patient that seven days before the occurrence of the malarial symptoms he had been severely bitten by mosquitoes. Of the records of 1900 hospital cases of enteric fever occurring in soldiers during the Spanish-American War, collected by the speaker, coincident malarial infection was found to exist in three per cent. of the total number.

Certain of the local newspapers continue to voice all sorts of weird and astonishing rumors anent the "startling revelations" promised as the outcome of the investi-

gations now being made concerning the bribery charges in the late examinations held by the State Board of Medical Examiners. Political influence is alleged to have played no modest rôle in the scandal, for it is said to have secured for more than one protégé of the State "machine" true copies of the examination papers well in advance of the time of the examinations. Physicians are quoted as declaring that direct bribery will secure from mysterious sources the examination questions, provided the pecuniary inducement is sufficiently great to meet the requirements of the briber. State legislators are alleged to have remarked that it is an easy thing for them "to take any man through the examinations," for they "have already done it." Stories are told of one progressive medical institution in which it is reported that a fund of $500 was raised by a clique of its students to "purchase" the official papers of the State Board last spring.

These charges, whether true or false, leave a nasty taste in the mouths of the laity, and it is hoped that they may be speedily and utterly refuted, for the very existence of such rumors, scandal, pure and simple, though they may be, sets a certain degree of reproach upon the medical profession at large, by reason of these reflections upon the honesty of the medical student body. The president of the State Board is vigorously pushing these investigations, and the charges, if substantiated, will result either in the re-examination of a large number of last year's graduates, or the summary forfeiture of their licenses to practise medicine in Pennsylvania.

The prosecution of dealers who attempt to palm off on the public oleomargarine as pure butter is still continuing in all sections of the city, and almost daily arrests and prosecutions are being made, followed, happily, by a large percentage of convictions of violation of the pure food laws. In the present series of prosecutions fourteen indictments have been made in the United States Court, and no less than ninety other cases have been brought to terms in the Court of Quarter Sessions.

The Board of Education has made arrangements with the faculties and trustees of the medical colleges and hospitals of this city for the formation of a corps of medical inspectors, to visit each day the public schools, and make a thorough personal inspection of all school children who may show symptoms of illness. The work of these supernumerary inspectors will supplement the duties of the regular medical inspectors attached to the Bureau of Health, whose time is so occupied at the present moment with the care of diphtheria and other infectious diseases that they are unable to give proper attention to the very important prophylactic duty of school inspection.

An illustration of the dangers which may attend the application of the hot-air method of treatment is found in the reported death of a patient in one of the city hospitals from burns received while endeavoring to free his limb from the intense heat of the apparatus with which he was being treated at the time of the accident. The patient, a sufferer from rheumatism, is reported to have become unruly and excited during the treatment, and, maddened by the heat and by fear of the procedure, kicked the apparatus from the hands of the attendant, overturning it upon himself. His clothing became ignited, and before the flames could be extinguished the man received burns about the upper part of the body, from which he died several days after the accident.

By the will of George W. Rexamer, which was admitted to probate during the present week, an estate valued at between $150,000 and $200,000 is devised to the managers of the Episcopal Hospital, after the death of the donor's wife and sister-in-law, to whom the income of the estate is left during their respective lives. The principal bequeathed to the Episcopal Hospital is to be used for the erection of a ward or building to be known as the "Rexamer Ward or Building," as the case may be.

Dr. John B. Deaver has tendered his resignation as a member of the visiting staff of surgeons of the Philadelphia Hospital, to take effect immediately. After accepting the resignation the Board of Charities (the governing body of the hospital) at once adopted an amendment to the rule fixing the number of members of the various visiting staffs of the hospital, so as to reduce the number of visiting surgeons from ten to nine. Thus, no successor to Dr. Deaver will be appointed, and the applicants for his former position, though strongly backed, were forced to face a technicality from which there was no appeal, for no vacancy exists.

Dr. Albert Fricke, one of the oldest living physicians in this city, died on November 17th, at the age of eighty-seven years, after a protracted illness, which, nevertheless, did not interfere with the performance of his professional duties until just before his death. Dr. Fricke graduated from the Medical Department of the University of Pennsylvania in the class of '35, and was associated during an earlier part of his career with the Pennsylvania and German Hospitals.

At the last meeting of the Mutual-Aid Association of the Philadelphia County Medical Society, held during the present week, the following officers were elected to serve for the ensuing year: President, Dr. John B. Roberts; vice-presidents, Drs. M. S. French and N. Hickmen; secretary, Dr. M. O'Hara, Jr.; treasurer, Dr. Joseph S. Neff. Nine directors, to serve for terms of three, two, and one years, were also chosen.

Dr. George Fales Baker has given the sum of $5000 to the University Hospital to endow a bed in memory of his father, Alfred Gustavus Baker.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

INEFFICACY OF THE INEBRIATES ACT—THE "MERCIFUL MAUSER" BULLET—FIVE DEATHS FROM ALCOHOLISM—SUCCESS OF CAMBRIDGE MEDICAL SCHOOL—AN ARCHBISHOP'S PLEA—SNAKE BITES IN INDIA—DR. JOHN ARLIDGE AND HIS WORK.

LONDON, NOVEMBER 12, 1899.

IT is a matter of serious regret to our profession, the world over, that the new English "Inebriates Act" remains to a large extent a dead letter on the Statute-

books. It was hailed, and rightly, as the crowning triumph of the life and work of the late Dr. Norman Kerr, and final justification of the views so long held by our profession, that the drunkard was to be treated rather as a patient than as a criminal. The provisions of the law were admirable, but as already alluded to in our former letters no arrangements were made for providing the funds for the construction of Detention Asylums suitable for this class of case, and disgraceful to state, this condition of affairs remains unmodified with the exception of a few cities where the local authorities have had the enterprise to provide such homes. Elsewhere the commitments under this Act have simply the choice between going to private institutions qualified to receive them or being sent to an ordinary prison. And as the private institutions aforesaid can only accommodate about a tenth of the number convicted, the result is, that magistrates very properly objecting to sending cases of this type to jail for an indeterminate period, either refuse to convict or go through the form of conviction, and then finding no accommodation other than the regular prisons, suspend the sentence. Several cases of this distressing miscarriage have occurred within the past week, one at Lancaster in which the drunkard was solemnly sentenced to three years' detention in an inebriate asylum. No such asylum was to be found in the County, and the man was simply sent to jail while the magistrate communicated with the Home Office. Three years in jail would certainly be about as wasteful and useless a remedy for chronic inebriety as anything that can well be imagined.

The reports from the seat of war fully endorse the reputation of the "merciful Mauser" bullet, which it won in our recent campaign in Cuba. It makes a clean wound with no splinters and passes directly through either the limb or part of the body, without lodging or twisting from its course, so that unless a vital organ is directly penetrated few complications develop and the wound heals with remarkable rapidity. As a weapon in civilized warfare, where there is no danger of the wounded being butchered, it would seem almost ideal; resulting in either a clean kill or a disabling wound which is rapidly recovered from, and in any case causing an amount of pain which is a mere trifle compared with the ragged wounds of the older bullets. The only exception to these clean and excellent results is in the case where the bullet is so much spent that its velocity is markedly diminished, or where, from ricocheting from the ground or rocks the nickel cover becomes broken, in which case it spreads and splinters as badly, or in some cases even worse than the old-fashioned soft bullet.

A further illustration of the double tendency toward alcoholism in a certain class of the community, in the direction of greater moderation and a more general use of beers and light wines, and another in another class towards the greater excess in the consumption of the spirituous liquors, has just been furnished by the recent experience of Glasgow. So great is the increase among a certain class of the working people not only in the consumption of whiskey, as pointed out recently by the "Lancet," but also in the intemperance in its use, that several manufacturing firms have found it necessary to change their pay day from Thursday to Saturday, in order to give their employees Sunday to sober up in! Unfortunately it would seem that the granting of this additional lee-way had resulted in even more unrestrained indulgence than before, for the Police department of Glasgow makes the appalling report this week past that no less than five persons were found dead in their beds on Sunday morning as the result apparently of excessive indulgence in alcohol the night before. If this rate be kept up, it would certainly seem as if Dr. Archdall Reid's theory, that alcoholism was diminishing itself by eliminating the intemperate element in the community, was about to receive a practical demonstration.

All who have noted the magnificent manner in which the University of Cambridge, chiefly under the direction of that master mind, Sir Michael Foster, has been gradually building up a School of Medicine upon the broadest and most modern and scientific of lines, will be delighted but not surprised to learn that it has already, this year, achieved the distinction of the enrolment of the largest number of students for the full medical course than any Medical School in the United Kingdom. This is not only a triumph of a scientific and philosophic spirit in medicine but ought also to serve as a much needed and most valuable incentive to the great London Medical Schools which are thus distanced in spite of their magnificent clinical opportunities, to look to their laurels and reform their methods. The success of the Cambridge Medical School has been due partly to the fact that it is in the hands of broad and liberal-minded scientists, instead of, to too great an extent, in this city in the care of busy consultants obliged to consider many of its problems with a view to the "main chance," but secondly, if not chiefly, that it is absolutely unhampered by any petty jealousies and narrowness which so deplorably mark the work of the London Schools. Without prejudice in favor of its own graduates or even its own nationality, where it has seen a great mind in any part of the realm of medicine or in any country it has properly availed itself of his services, and its career of success is only just beginning.

An address which has attracted much attention in medical circles was that of the Primate of the English Church, the Archbishop of Canterbury, at St. George's Hospital Medical School, where he presided at the distribution of prizes. With the intensely practical turn which marks all of Dr. Temple's utterances, he called attention to the significant fact that while the sum of truth to the theologian was to some degree fixed and determined, to the scientist it was not and could never be so. Hence he vigorously urged not merely the desirability but the absolute necessity of continual study, investigation and self-improvement upon the part of the medical man all the days of his life and practice, an appeal which will do much to further the incipient growth of the post-graduate spirit in the minds of the English profession.

An astonishing impression of the relative helplessness of man, the animal, in the tropics, in the face of the terrible foes which he has to contend with among the other forms of life is produced by the recent report published from India

that no less than 25,000 deaths have occurred during the past year by the attacks of wild animals or by snake bites. We are, however, warranted as medical men and students of human nature in exercising a little healthy scepticism as to the actual character and species of "wild beasts" and "snakes" concerned in this great mortality. For it is, of course, one of the open secrets of medical men practising in the tropics that "snake-bite" is an extremely convenient term for covering the sudden disappearance or discovery of the corpse of any individual whose room would be more welcome than his company. Under a tropical sun the frightful rapidity of putrefying changes after death from any cause and the distortions due to them are absolutely indistinguishable within 24 or 28 hours from the very similar ones produced by the toxins of snake-bite. And many painful cases have occurred, for not only members of the native community but even European officials and members of our own guild have suddenly died in out-lying stations from this alleged cause, and long before expert examination could be made of the body it was one mass of putrefaction from which no evidence of the administration of poisons or even of the presence of stab wounds of moderate width could be elicited by examination. From the days of Joseph and his brethren "some evil beast hath devoured him" has been the most convenient excuse of the murderer, and the increased security of modern life has been due in no small measure to the fact that its conditions have rendered these two convenient explanations absolutely inadmissible and practically made every death traceable to some definite cause that could be detected on post-mortem examination. What possible headway could we make with food poisonings and drug poisonings other than metallic salts, if it were possible to set up snake-bite as an explanation of the presence of toxins and ptomaines?

Another hero reformer of our profession, whose reward however consisted, as is generally the rule with us, in the consciousness of having done his duty, rather than in fame or other emoluments, has just passed away in the death of Dr. John Arlidge of Stoke. His patient researches into the dangers of modern industries were the beginning and the foundation of the movement for the protection of the working-man which culminated in the Factories Inspection Act of England. Practising as he did in the midst of the Potteries where the fearful results of lead-poisoning in those engaged in this industry were brought to his notice, Dr. Arlidge carefully studied the situation, collecting information and searching out remedies, and by persistently bringing his results before the public succeeded in opening their eyes to the fearful risks which attended certain occupations. These were, of course, at first declared to be absolutely inevitable, one of the penalties of modern civilization and so forth. But Dr. Arlidge would not have it so, and time has abundantly vindicated his position and shown that with a few exceptions almost every one of these risks can be avoided by proper ventilation, cleanliness and care on the part of the employer and employee. And as another of the illustrations of the strength of right in this world, by which the physician is so often cheered, this improvement has not only diminished the mortality of the workers and increased their general health and comfort but actually also improved the effectiveness of the industries concerned instead of crippling them, as the almost unanimous outcry was at first.

THE PLAGUE IN SOUTH-AMERICAN PORTS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I gather from the Uruguay newspapers received to-day and from letters from friends in that part of South America certain details with regard to bubonic plague in Paraguay which I feel sure will be of interest to your readers. Up to the latter part of October the disease had not left Paraguay. Only a single suspicious case has been found in the Argentine Confederation, in the territory of the Missions. The governments of Uruguay and the Argentine Confederation, of Chili and of Brazil have taken the most stringent precautions. There is the greatest fear that the disease will spread. Just as soon as it was known definitely that a disease suspected to be plague had succeeded in gaining an entrance, the Argentine government sent a commission for the purpose of studying it. The preparation of an antibubonic serum was immediately begun in the bacteriological laboratory of Montevideo in order to be prepared for any emergency that might arise from the invasion of the disease.

While the commission sent by the Argentine government is convinced that the cases are true bubonic plague, certain physicians of Paraguay deny this, and assert that the disease under observation is an ailment which is rather frequently observed in their country. The clinical description, however, published by the physicians called to treat the cases are confirmed by the bacteriologic investigations and the experiments performed in the laboratories of Montevideo and of Buenos Ayres, and both these sources of evidence make it clear beyond doubt what the true nature of the disease is.

The disease continues to advance slowly but surely in Asuncion, the capital of Paraguay, where at the beginning the cases were very rare. At first one new case on an average was reported every three days. Since the first of October, however, the new cases averaged almost three a day. This is the usual conduct of the plague, and often disarms suspicion of the real character of the disease. For some time after its invasion of a new locality it claims but few victims, and limits itself to certain narrow foci, but soon is propagated with great intensity. The present epidemic began at Bombay in just this way. At Oporto, where the disease has existed now for more than three months and half, though the number of cases is less than a hundred, we cannot be sure for that reason that the future course of the disease will be a mild one.

One of the old physicians of Paraguay says that there exists in Asuncion a small stream made up mostly of stagnant pools which traverses the part of the city occupied by the poorest of the population, and receives all the filth of the city. This filth is not carried away at once, but stagnates and ferments under the

extreme heat. This, with the absence of public sewers, is amply sufficient to account for almost any epidemic even without the necessity for the introduction of a microbe from India.

It is certain that the plague is spreading in Paraguay, and though the epidemic is not as severe as true bubonic plague has often been in history it has a mortality at least of fifty per cent. When the disease first broke out its mortality was very alarming. Of the twenty-three persons first attacked twelve died. From the quarter of the city where it first appeared the disease spread to a group of houses situated along an arm of the river where the population is rather thick, inclined to be filthy, and in frequent contact with the soldiery. From these quarters it has spread practically to all parts of Asuncion that are not over clean.

The physicians who believe that the disease is without doubt genuine bubonic plague, assert this not only because of the bacteriologic investigation, but also because of the epidemiologic character of the disease. In virulence the microbe certainly at least equals the bacillus of pest. Dr. Decoud has seen a number of patients who have died of the disease in from thirty to forty-eight hours. Clinical symptoms are extremely simple. There is sudden fever, swelling of the glands, congestive spots, and then rapid death, or in place of death a slow and painful convalescence, accompanied usually by suppuration, sometimes by resolution of the affected glands.

Dr. Decoud also believes that the infection is being carried by fleas. In confirmation of this interesting opinion the doctor points out that the swelling of the glands always follows a series of minute punctures which indicate the points of entrance of the affection. For instance, when the flea-bite occurs in the leg they can be seen very plainly still present when the inguinal glands become enlarged. In the arm the axillary group becomes affected and the flea-bites can often be seen on the fingers or hand.

The disease as it exists in Paraguay is running a course very like the affection which Favre described in a recent number of the *Zeitschrift für Hygiene und Infektionskrankheiten* and which he has observed in certain provinces in Russia. The disease begins with an elevation of temperature and an intense headache. Then frequently there is vomiting and diarrhea, though often a certain amount of constipation is present. The buboes which appear in the axilla or inguinal regions are extremely painful. It is usually not hard to trace the history of contagion either from individuals affected by the disease or from objects that belonged to them. There is no typical period of incubation and all ages are equally liable to the disease. The mortality is very high and cures very rare. The sole difference between the disease and genuine plague is its lesser tendency to spread. From letters from Uruguay by friends here I have reason to know that the fear of the disease in Uruguary is very great. Especially since the news has been given out that a second Sister of Charity has fallen victim to the disease. Neither the government itself nor the inhabitants of Asuncion are reporting all the cases that exist. It appears that the true number of those attacked is at least double that reported.

Sincerely yours,

FELIX VITALE, M.D.

COYTESVILLE, NEW JERSEY,
November 18, 1898.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON SURGERY.

Regular Meeting Held November 13, 1899.

THE Chairman of the section, DR. CHARLES N. DOWD, in the Chair.

DR. HOWARD LILIENTHAL of New York presented

A CASE OF PURULENT PERICARDITIS SUCCESSFULLY OPENED AND DRAINED

It was operated on during the summer and seemed interesting because the amount of pus evacuated made it almost unique in character. The patient was a Russian, 15 years of age, who on July the 6th of the present year was admitted to the Mt. Sinai Hospital. He had at the time the symptoms of a trilobar pneumonia. Two of the lobes of the right lung and one of the lobes of his left lung were consolidated. His temperature was 104.5 °F. when he came into the hospital, and it rose to a 105.6 °F. after a day or two. There was a steady progression of the symptoms. On July the 10th his respirations were 66, on July the 11th, 68. Pneumococci could be found in the sputum, but no tubercular bacilli were present. Prostration was so great that the patient could not urinate and the catheter had to be used. On the 13th the respiration rose to 72, on the 14th a pericardial friction sound was heard. No increase of heart dulness could be demonstrated for two days however, then it was noted that the sternum was flat from the notch to the ensiform. Streptococci were now found in the sputum, but tubercle bacilli were absent. After a remission of symptoms for more than ten days the pericardial friction sound returned. This was the beginning of August. Ten days later his condition had become very miserable. His pulse rose to 145 and was weak and irregular. On the 14th of August he was aspirated for the pericarditis and 18½ ounces of pus were removed. It was found to contain a pure culture of the pneumococcus. As he did not improve he was transferred to the surgical ward. Considerable cyanosis had developed, and as the patient was very nervous the question of anesthesia for the operation which was evidently indicated was a very serious one. It was decided that ether could not be given because of the struggling that might ensue. Chloroform it was feared might induce syncope in the weakened condition of the heart. Local anesthesia was decided on and as the patient was very fearful he was not told that an operation was to be done but made to understand that more thorough aspiration was to be tried. The local anesthetic used was eucain B. His face was screened off by a towel so that he might not see the site of the operation.

The patient was given five minims of Magendie's solution ten minutes before the operation. Altogether one dram of eucain B was used to produce the local anesthesia. The incision was made from the third to fifth intercostal space, about a quarter an inch from the sternum and then was given the form of L by an incision towards the nipple. Three quarters of an inch of the costal cartilages were resected. Fortunately the interspaces were wide and gave plenty of room for the surgical manipulations. When the pericardium was reached it proved to be extremely thick. Tissues at least a half inch in thickness had to be cut through, Immediately after penetration there was a tremendous gush of pus, at every little cough there would be another gush of pus. Several times when it was thought that all the purulent material had been evacuated movements of respiration or of coughing would expel more. It was estimated at the time by one of the assistants that thirty-five to forty ounces of pus were removed. Personally the amount was estimated at nearer fifty or sixty ounces.

A drainage-tube was tried, but it impinged upon the heart and it was feared that the friction might cause erosion or reflex nervous trouble in an already weakened organ and so the wound was left open, no artificial drainage being employed. Irrigation was employed a number of times and the normal salt solution used for this purpose seemed to become pocketed in the pericardial folds and gushed out on cough or respiratory efforts, as the pus had done. The patient three months after the operation is in excellent general condition. Synechiæ have formed but the youth of the patient will probably lead to the gradual tearing loose of these as he grows in strength and that ultimately he will be left with an untrammelled heart.

DR. MAURICE H. RICHARDSON of Boston then read the paper of the evening, entitled

REMARKS ON THE SURGERY OF THE GALL-BLADDER.

He begged to state that his paper should rather be called surgical intervention for gall-stones. There were a number of unsettled problems in the treatment of gall-stones which would require the accumulated experience of surgeons from all over the world in order to be solved. Gradually the fatality of operations on the biliary tracts is being reduced and it is evident that a great and successful field for modern surgery is being opened up. The subject is too large to attempt to treat exhaustively. I shall only try to give you some of the practical points that I have learned from my own experience. In this last ten years I have had under treatment altogether 153 cases in which the presence of gall-stones was suspected. In 95 of these operation was performed. In the last year 34 operations for gall-stones, and only 54 hysterectomies were done in the Massachusetts General Hospital. This gives a fair idea of the relative position that gall-stone surgery is gradually taking since operations for gall-stones are almost as common now as hysterectomies.

During the last year I operated in 21 cases with 2 deaths. In all my experience I have had 18 deaths. The collation of these deaths shows that the fatal termination was due more to the patient's condition before the operation than to the operation itself. A number of causes over which the surgeon may have very little control, such as uremia, embolism, capillary oozing, thrombosis, come in to swell the death-rate. The important practical rule is not to delay operation until the patient is so run down that it will not be well borne.

As to certain questions with reference to gall-stones this has been my experience. First, as to their bacterial origin, my brother, Dr. Mark Richardson, has examined very carefully all of my cases for this purpose and the result was negative. There is no proof of definite bacterial influence in the formation of gall-stone. An important thing is the form gall-stones may assume. This causes them sometimes to cling to the mucous membrane and makes their removal a matter of difficulty, while it influences also the possibility of their engagement in the biliary ducts and also the possibility of their making a water-tight impaction. It is this that is the main cause of intermittent jaundice. The gall-bladder may, however, distend in other directions more toward the median line, for instance, or toward the umbilicus or even toward the iliac fossa. This is important.

I have found as many as 540 stones but in this case there had been fewer symptoms than in a patient from whom I removed a single irregularly shaped stone. The absence of facets on a stone does not necessarily show that other stones are not present. I have found as many as ten unfaceted stones in a gall-bladder.

Symptoms from stones are most irregular. I have removed a stone that was large enough to cause blocking of the small intestine yet it did not give the slightest history. In my experience a normal gall-bladder, even if moderately distended, cannot be felt. I have found it very difficult to decide when a gall-bladder was tensely distended as to whether it might not be a kidney, or some pathological condition of tissues in this neighborhood. At times a tensely contracted gall-bladder, especially where the contraction is due to the reflex action of the presence of gall-stones, simulates malignancy. Once I was on the point of giving up an operation because it seemed absolutely hopeless to proceed for this reason. Yet the patient made a good recovery and the symptoms have all disappeared. It must be borne in mind that the mucous membrane of the gall-bladder after the relief of pressure by the evacuation of the accumulated contents bleeds very easily. The surgeon should permit himself only such manipulations as are absolutely necessary. I have had one very sad fatal case in the person of the wife of a physician friend. No single vessel of any size was involved, but extensive capillary oozing took place from every part of the surface of the mucous membrane of the gall-bladder. It is evident that operations should not be delayed too long. If complications have not already set in there is practically no danger.

The diagnosis of gall-stones is an extremely important matter and is the concern of the surgeon rather than the physician, especially if operative interference seems essential. Pain is an important symptom but pain may be referred away from the region of the gall-bladder

even to widely distant organs. Another important symptom is the distention of the gall-bladder. It usually comes forward toward the abdominal wall just beneath the edge of the liver as an ovoid, the other end of the long axis pointing toward the foramen of Winslow. This distention may close up the hepatic duct and the intermittent jaundice that is sometimes noticed is caused by alternating stoppage and relief from pressure.

The pathognomonic sign of gall-stones is the finding of a stone in the stool. Sometimes other symptoms are so marked as to render careful exploration of the stool unnecessary, at times most careful search will fail to reveal the presence of a stone. The absence of a stone in the stool is not positively negative, because the pain may have occurred from a stone that was just grasped by the biliary passages and then released. One source of mistaken diagnosis in gall-stones that is not sufficiently considered is appendicitis. Oftener than might be imagined not only is the pain of an appendicitis referred to the region of the liver, but the tumor appears in a position that might easily be assumed by a distended gall-bladder.

In general, when there are any serious symptoms and yet good grounds for doubt remain as to whether a gall-stone is present or not an exploratory incision is indicated. Even if the tumor seems to be malignant, this exploratory incision should be made. This is very important. The patient is given a good many chances for a very trivial danger. Even after the incision is made the thickened walls of the tensely distended gall-bladder may simulate a malignant tumor. After incision and removal of the gall-stones, the bladder promptly returns to almost normal. No further symptoms may develop. Nature is a poor operator. What the surgeon is able to accomplish in a few moments of skilful work with the knife nature will take years to do and then the result is by no means something to be proud of. Palliative treatment for gall-stones giving serious symptoms is practically always a mistake. Besides stones in the gall-bladder there may be stones in the biliary duct. These are much more difficult to treat. As a general rule the duct should be incised immediately over the stone and the stone removed, drainage being provided so as to permit the escape of bile or any other fluid that may collect around the parts. The persistence of biliary fistulæ in these operations often indicates that a stone further down has been left in the bile passages. If the cystic duct is incised for the removal of a stone it may be well to remove the gall-bladder and sometimes the duct also. The chronic irritation which causes thickening of the gall-bladder may lead later to carcinomatous degeneration of the tissues of the bladder-wall. Gall-stones are well known to be a serious etiological element in the production of cancer. In operations on the common duct it is to be remembered that the portal vein runs by the side and that folds of it may even overlie the common duct in the lower part of its course. It may easily be injured and a fatal issue is inevitable unless the rent can be repaired. I know of one case where Lembert sutures were applied to a cut portal vein and though furious hemorrhage had resulted the patient's life was eventually saved. With the modern development of surgery the surgical relational anatomy of the portal vein is much more important than that of the triangles of the neck.

It is to be remembered that even the slight manipulation in malignant disease may cause a fatal termination by causing uncontrollable bleeding from vessels in the midst of the malignant tissue where it is often impracticable to control hemorrhage. The ideal operation, of course, after the incision of the gall-bladder to remove gall-stones would be to close up the incision in the fundus by a series of Lembert sutures and then seal the abdominal wound. I have tried this twice where the conditions seemed eminently suited to guarantee a good result from it. In both cases I had forty-eight hours of most serious uneasiness with regard to my patient. I have abandoned this ideal procedure entirely and do not think I shall take it up again. Temperature and pulse in both cases rose to such a degree, the patients' conditions so affected and their convalescence so disturbed by untoward events after operation that I shall not easily be persuaded to try it again. I have reason to know that this same distrust of this so-called ideal operation exists among my colleagues at the Massachusetts General Hospital.

In discussion Dr. Robert F. Weir of New York said that he agrees with Dr. Richardson as to the advisability of leaving the gall-bladder open. After the incision he attaches the edges of the tissues to the abdominal wall or to the peritoneum or to the deep layer of fascia and leaves the skin incision open. Usually a drainage-tube gives excellent service. Kehr with his large experience leaves the incision open. Sometimes when the lower bile passages seemed to be closed he forces an opening by injections of water not using much pressure of course. This gives better chances of satisfactory recovery in my experience. With reference to operations on the ducts I usually make the incision at the upper portion of the duct where there is much less danger, practically none in fact, of wounding the portal vein during the manipulation. With my finger in the foramen of Winslow I feel myself master of the situation and can hold myself in readiness for whatever procedures are necessary. I have found the suturing of the common duct an extremely difficult thing to do satisfactorily, I used Lane's long, thin, needleholder, but abandoned it after one or two trials. Halsted's hammer for the same purpose also proved unsatisfactory. In the last six cases I have simply left the wound open and allowed it to drain from the bottom and have been very well satisfied with the result.

After removing a stone I used to employ a sound in order to demonstate whether the duct was patulous beyond the point where the stone had been lodged. I feared, however, that I might introduce septic material from the bowel, so now I introduce water from a long-nozzled syringe made for the purpose. I have had gall-stones produce perforation in three cases with extravasation of bile. In one case this flowed down into the right iliac fossa and there was mistaken for appendicitis, until after incision the yellowish-colored fluid was found.

Dr. Charles F. McBurney of New York said: The more I know of gall-stone surgery the more respect

I have for the lesion. It is by no means an easy branch of surgery and there is no doubt in my mind that its invasion without careful preparation and experience will lead to a good many sad results. Gall-stones often give no symptoms. They are often discovered at operations and autopsies without the slightest inkling of their existence. Sometimes after having given symptoms for a time they cease to be troublesome.

I often feel like leaving certain cases alone. In elderly people who do not stand operations well and in fat people in whom the manipulations are much hindered by the thickness of the abdominal wall, I generally do not advise operation unless the symptoms are absolutely unbearable. Otherwise the earlier the operation is done the better the chance of success. Biliary fistulæ after operations on the gall-passages are extremely annoying. Dr. Jones of Rising City, Nebraska, has I think, demonstrated the best method by which they can be avoided. He inverts the coats of the gall-bladder so as to bring the peritoneal surfaces together. The incision then closes very prettily. His work was done on dogs but I have seen it substantiated in the human being. When stones are in the common duct instead of cutting directly down upon them, I prefer to make an incision into the duodenum and take them out through the duodenal papilla. There is no need of abdominal drainage then after the operation, the surgeon need have no anxiety and all danger of wounding the portal vein is avoided.

DR. FARQUHAR CURTIS said: Bleeding occurs in operation upon the biliary tracts only in rare cases. It seems that there is some special reason for this. In one case in which I was bothered for a long time after operation by almost uncontrollable capillary oozing, cirrhosis of the liver developed and brought on a fatal termination after some months. It was then evident that the hemorrhage in the case had been due to the destruction of the portal circulation. I agree very heartily with those who insist that an exploratory incision should be made in cases where malignancy is suspected. The patients are given a chance for their lives. It will be found that sometimes malignancy does not exist, but has been simulated by the presence only of gall-stones.

DR. ROBERT ABBE said: At times in operations upon gall-bladders in which stones have existed for sometime great hypertrophy of the tissues will be found to exist. In one of my cases so massive was this hypertrophy that the walls of the gall-bladder were an inch in thickness and cut like a potato. I gave an absolutely bad prognosis because I felt sure that the tissues were malignant. In six months the tumor had completely disappeared, the patient has since continued without a symptom.

DR. JOHN B. MURPHY of Chicago said: I am very glad to hear it claimed here to-night that gall-stones are practically always a surgical lesion. I am also very glad to find that others realize the danger from hemorrhage in these operations on the biliary tracts. I had my sad experiences with this important factor in my early operations on the bile passages and it proved a great source of discouragement. I now make it a rule where jaundice exists to do as little operating as possible. I prefer to do a preliminary cholecystostomy, in order to get rid of the jaundice, waiting for some time for this purpose and then after some days or weeks I do whatever further operating seems necessary.

In closing the discussion DR. RICHARDSON said that he did not consider old age a positive contraindication to operation. He had had one patient of 78 who could not stand the pain of the gall-stones and who did stand the operation well. When incisions are made in the common duct he considers that the safest way is to drain and allow the wound to close of itself. In reply to a question of Dr. R. Morris he said that he did not know why facets did not occur in certain cases despite the presence of other stones. He had not noted whether adhesions existed or not in these cases.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 7, 1899.

FREDERICK PETERSON, M.D., President of the Society, in the Chair.

MULTIPLE NEURITIS AND ACROMEGALY.

DR. WILLIAM HIRSCH presented a man, twenty-six years of age, who had come to his clinic on July 14, 1899, complaining of shooting pains in the upper and lower extremities, and great difficulty in walking. He stated that seven years ago he had had a similar attack of pain in the upper part of his body, and had been paralyzed for six months. Two years later he had had a similar attack, lasting ten weeks, and there had been a third attack, though of shorter duration. Examination had revealed very marked atrophy over the muscles of the upper extremity, especially the muscles around the shoulder. The long muscles of the back were also considerably atrophied, as were those in the lower extremities, but not to the same degree. Sensation was slightly diminished in the shoulder girdle. The motor power had been greatly decreased so that the man could walk only with the greatest difficulty. The pupils were equal and of normal reaction. The patellar reflexes were considerably exaggerated, but there was no ankle-clonus. The case was evidently one of recurrent multiple neuritis, but in addition there was a distinct swelling of the upper lobe of the thyroid gland, and his hands and feet were disproportionately large, and more or less disfigured. The bones of the carpus and metacarpus were decidedly thickened at their ends. The internal and external condyles of the femur were much thickened, and the lower jaw was not of the usual shape. The heart was enlarged, and there were systolic and diastolic murmurs at the apex. The patient stated that he had noticed a gradual enlargement of the hands and feet since the age of twenty-one, and, according to his statement, he had grown about two inches in height during the last few years. A diagnosis of acromegaly had been made. Plaster casts of the hands and feet had been taken at that time. The man had been placed on the extract of hypophysis. He had recovered from his neuritis in about two months, so that he could now walk perfectly well. There had been such

a marked diminution in the size of the hands during this period that casts made two days ago were also presented to allow of comparison with those first taken. Skiagraphs showed that the chief changes had been in the soft tissues. The speaker said that the recurrence of multiple neuritis seemed to be quite in harmony with the theory that the acromegaly was the result of a disturbance of metabolism from disease of the hypophysis.

DR. W. M. LESZYNSKY said that the case seemed to him an atypical one, and he would not be willing to accept this diagnosis until a careful examination for spinal curvature had been made, and the visual fields had been tested.

DR. TERRIBERRY asked what Dr. Hirsch considered to be the pathological condition giving rise to the neuritis. The existence of fibrous enlargement of the joints would point rather to the case being a neuritis of rheumatic origin.
